ANNALS OF INTERNAL MEDICINE

VOLUME 8

JULY, 1934

NUMBER 1

PRESIDENTIAL ADDRESS

By GEORGE MORRIS PIERSON, M D , F A C P , *Philadelphia, Pennsylvania*

It has become one of the customs and traditions of the American College of Physicians each year to accord to the retiring President the privilege of formally addressing the society. As I undertake to fulfill this pleasant obligation I heartily wish that I possessed the sagacity and skill of the late Dr Francis Delafield who, on the occasion of the first meeting of the Association of American Physicians, delivered an address that rivalled in completeness, wisdom and brevity the oft quoted Gettysburg speech of the immortal Lincoln. Dr Delafield's remarks occupy a little short of one page of the transactions of the Association. Although I cannot hope to emulate his achievement I can, however, put your minds at rest with the assurance that I shall do my best not to trespass too long upon your time and patience in what I have to say.

The months that have intervened since our memorable Clinical Session in Montreal have been fraught with events of international as well as national importance. Unbelievable changes of political, social, economic and industrial significance have taken place. Every social group, physicians along with all others, has been profoundly affected. As the result of these altered conditions, the American College of Physicians, together with other organizations, has had to meet unusual and unexpected problems as well as unprecedented economic situations. It is with considerable pride, therefore, that we are able to come before you at this time secure in the knowledge that in spite of the difficult conditions that have existed, the American College of Physicians has thus far come through these turbulent times unscathed.

The losses from the ranks of our Fellows and Associates by death and resignation have been more than offset by the additions to our membership, so that today the total enrollment in the College is 3,100. Furthermore, none of the essential activities of the College has been given up or seriously curtailed. This satisfactory state of affairs is due in large measure to the excellent business judgment, alert watchfulness, and painstaking economy that has been exercised by your Executive Secretary in his efforts to manage the affairs of the College in strict accordance with the wise, far-sighted and

* Read at the Chicago meeting of the American College of Physicians April 18, 1934

conservative policies laid down for him by your Board of Regents and Board of Governors all of whom richly merit your confidence and support I wish to take advantage of this occasion to express to them my personal appreciation of the never-failing interest they have shown in the College and to thank them for the loyal and helpful support they have accorded me, without which your presiding officer would have been unable to direct the affairs of the society with any measure of success

A survey of the addresses of some of my distinguished predecessors as President of the College, discloses the fact that it was not unusual in the past to devote considerable time to a justification of the College and its purposes. Such a discussion today is wholly superfluous in the light of the progress and achievements of the College during the past decade. No more convincing proof is needed that the College has amply justified its existence and now occupies a permanent and unique position among the medical organizations of this continent, than is afforded by an examination of the Roster of our Fellows. It now includes a very great number who, by reason of their outstanding accomplishments in various fields of internal medicine and allied medical sciences, have not only achieved distinction as clinicians and teachers, but have also contributed liberally to the great advances that have taken place in Clinical Medicine during the last quarter of a century.

If time were available it would be both interesting and profitable to enumerate the truly outstanding contributions to the progress of medicine that can be attributed to the Fellows of this College. Moreover, we are particularly fortunate not only in having Fellows who have been and are leaders in medical thought, but in being able to number among our membership a large group of younger Associates, many of whom have already, or soon will have acquired prominence as internists. In these Associates lie the real strength and scientific hope of the College. It is not enough for an organization to number among its members those who have attained distinction, if it would prosper and extend its influence it must be nourished by a steady influx of those who possess the potentialities for future accomplishment.

It has frequently been said that if the American College of Physicians had done nothing else than to inaugurate and successfully conduct its Annual Clinical Sessions, it would have amply justified its existence. With each succeeding year these Sessions have attained greater importance and greater scientific interest. They are unique in that they bring together from all parts of the country, under unusually auspicious conditions, the largest group of men who are primarily interested in all the many and varied aspects of Internal Medicine in its broadest sense.

As popular and successful as these meetings have become, we must not rest content with our present accomplishment. We must be constantly on the alert to find ways and means of improving these Clinical Sessions. Every effort should be put forth to have the outstanding work of the year

that is of interest to clinicians reviewed at our Sessions. In this way large and interested audiences will be assured. It is a well known fact that the prospect of an adequate and discriminating audience is a most effective stimulus to good scientific effort. If we consistently make such audiences available at our meetings, we shall provide an inspiring setting that will soon make those who are doing worthwhile work more eager to present the results of their labors before this College than elsewhere. The hope of having an opportunity to participate in the program of our Clinical Session should prove a constant stimulus to our Associate members. It is not too ambitious to look forward to the day when the gatherings of this College will hold such a conspicuous place among the medical meetings of America that the majority, at least, of the important advances in clinical medicine on this continent will be given to the world through the medium of the American College of Physicians.

It seems not inappropriate at this point to turn away from these questions that involve chiefly the interest and welfare of the College and consider for a moment certain problems that are of fundamental importance to the members of this College as well as to the medical profession as a whole.

Since the world became engulfed in a wave of economic and social unrest associated with widespread financial depression, a number of problems of sociologic, economic and even political importance in connection with medical practice have engaged the attention of the lay public as well as the medical profession of this country. Indeed, in some localities these problems seem to have transcended in importance and popular interest all other aspects of medicine. The term medical economics has sprung into prominence of late and has quite generally been adopted as an expression to designate those problems that involve the various relationships that exist or can arise between physicians, on the one hand, and the public and the state on the other. It is unnecessary to enumerate the manifold problems that fall into this category. Let me hasten to reassure you at this point that your speaker has no intention nor desire to open up the already much debated, although still far from settled problems of medical economics.

The importance of these questions to the country at large as well as to the medical profession is undeniable, since they involve the fundamental problem of the public health upon which rests the happiness, prosperity and the very security of the nation. They involve complicated problems that must be solved and their solution will require mature deliberation and dispassionate as well as sober thought. After a long period of lethargy the medical profession is now aroused to the importance of taking an active interest in these questions, in the final solution of which it is earnestly to be hoped that our profession will take a leading part. Certain it is that if their satisfactory solution is not directed by the medical profession from within, some plan, however unwelcome and distasteful it may prove, will ultimately be forced upon the medical profession from without. Nevertheless, as vital as these issues are, the American College of Physicians hardly

provides the proper forum wherein to debate these moot questions. We are essentially a scientific body dedicated to the advancement of clinical medicine, we represent a group of physicians primarily interested in internal medicine. We are in no sense a cross section of the medical profession of this country. As individuals we are entitled to and should hold definite views on all matters involving the welfare of medicine and the community. As members of our National, County and State societies, we can be afforded ample opportunity to take an active part in moulding both lay and medical opinion on these social and economic questions. In our capacity as Fellows of the American College of Physicians it would seem best for us to see to it that this organization adheres purely to the scientific and educational purposes for which it was created. Let us not dissipate our energy, time and resources in costly investigations of and futile debates, which too often become acrimonious, upon subjects which, however important, do not fall properly within the scope of our activities. This is especially true when there exists a great national medical society which, by reason of its almost universal membership, equipment and organization is the one body best able to deal with these problems and to safeguard and readjust the interests of the physicians and the rights of the public.

Although admittedly, as an organization, we are not properly constituted to deal with the varied aspects of medical economics, there is no escaping the fact that as a group of scientifically trained men we have a real interest in the future development and progress of medicine. It is generally recognized that in medicine, as in virtually every other business and professional activity, marked changes have taken place. In the case of medicine, at least, some of these changes seem to have created situations that are not wholly satisfactory either to the profession or the public. Therefore, it seems timely and not out of keeping with the purposes of this College to review some of the factors that have been responsible for these changes and to consider how medicine may advance in the future in order to correct some of the difficulties that have arisen.

If we look back but a couple of generations we find that the practice of medicine was not surrounded by the difficulties and complexities that beset it today. At that period with few exceptions doctors were general practitioners, few specialists existed and even the outstanding surgeons of the day were not above or averse to the duties of general practice. The family doctor of former days has been so often extolled and his virtues and accomplishments have been so thoroughly praised that it is far from my intention to add to these richly deserved eulogies. Suffice it to point out that the general practitioner of the past was more than a physician, he was a socially minded individual who was an important factor in his community and was regarded with confidence and respect. His word was undisputed in all matters pertaining to health and disease. What he may have lacked in scientific training was more than offset by his understanding of and his keen personal interest in his patients and their problems.

In short, he furnished his fellow beings a medical service that was so generally available and so satisfactory that there was apparently neither the occasion nor the opportunity for the vexing problems involved in medical economics to arise.

Gradually, as the exact sciences were more and more applied to medicine, far reaching changes began to take place and what might be termed the modern era in medicine began. About the end of the last century, with the development of bacteriology, experimental physiology and pharmacology, biochemistry and the other medical sciences, medicine as an art began to decline and the science of medicine came into the ascendancy. With this trend medical teaching was altered, medical courses were lengthened, classes were restricted in size, premedical requirements were increased, scientists began to replace practitioners as teachers and medical students became imbued with the spirit of research and impressed by the importance of the science of medicine. Who can deny the inestimable value of this changed attitude to the progress of scientific medicine. As the result of all this most of the advances upon which modern medical practice is founded took place. In the last fifty years greater progress has been made in all fields of medicine than occurred during the preceding two thousand. But this era of scientific achievement has not tended to develop any widespread interest among medical students in general practice. On the contrary, it has created in many of them an ambition to pursue the more academic and scientific aspects of medicine to the exclusion of practice, while not a few who have gone into clinical medicine have made haste to enter special fields and have exhibited little enthusiasm for the hardships and inconveniences of the general practitioner.

The outcome of this modern trend in medical thought has been that while medicine, established upon a firm scientific foundation, has advanced to an unbelievable degree, the art of medicine has suffered.

The general practitioner, finding it increasingly difficult to keep pace with the rapidly succeeding changes that have been taking place in medical practice, has been gradually superseded either by out and out specialists or by a group of clinicians who by reason of their ultrascientific training have come to look upon patients more as interesting clinical material than as individuals seeking aid for illnesses that are quite as often dependent upon mal-adjustments in their domestic and social environment as upon objective pathological changes and which require for their correction a broad minded, sympathetic viewpoint on the part of a medical advisor. The public has become conscious of this fact. The intelligent layman, fully alive to the incalculable blessings that medical progress has bestowed upon him, is equally aware that as medicine has advanced it has become more impersonal and more specialized. He realizes that a medical examination today is apt to become a costly and formidable procedure devoid of much of the personal interest and understanding in his individual problems that was so conspicuous in the days when the general practitioner held sway. Although

medicine has changed, the psychology of patients has not. For the most part, they still manifest a desire for personal service much the same as they did in the times of our forefathers, in spite of the advances that have taken place in medicine.

One important result of all this has been that the public, finding that broadly trained, socially minded doctors were too often unavailable has gradually drifted away from the general practitioner and turned more and more to specialists and special groups. Where once a single physician cared for a patient and helped solve his problems now many are needed, all regarding the patient from some special angle, none being willing to consider him as a whole. As a consequence, as the prestige of the general practitioner has diminished the cost of medical care has increased. The passing of the general practitioner and the rise of specialism has beyond peradventure been an important factor in the much deplored increased cost of medical service.

Those who are concerned in medical education and the many economic problems that now confront us have gradually become aware of the necessity of altering in some way the training of doctors so that there may be available to the rank and file of the people of this country that to which they are justly entitled, a group of physicians who in a modern way can fill the gap created by the passing of the general practitioner of a former generation.

The pendulum of medical education which moved so far toward the purely scientific side is gradually swinging back. Medical schools everywhere show an encouraging tendency to select as their students not only those who show aptitude for scientific pursuits but those who have the preliminary education, social background and personality to develop into efficient practitioners of broad vision and high ideals actuated by an impelling desire to be of service.

To that end, the training of these men, either before or during their medical school days, should not be limited so strictly to biological and medical subjects, it should include the fundamentals of psychology, sociology and economics so that those who go forth into practice may be socially minded, public spirited citizens capable of taking a leading part in the varied activities of their community and of directing popular thought in all matters pertaining to the health and welfare of the people.

It is generally conceded that less than 5 per cent of medical students are qualified to go into the purely academic or research fields of the medical sciences. Dr. Roger I. Lee has recently shown that 85 per cent of medical practice can be successfully carried out by the family practitioner leaving but 15 per cent that requires the services of a trained specialist. From which it may be deduced that not over 10 or 15 per cent of medical graduates are justified in spending the time and money necessary to equip them as specialists, when the majority of any class are best adapted to general practice and should be trained with that in mind.

The "family doctor" of old is gone forever, but his counterpart must

he developed in the form of a physician possessed of an adequate cultural background, scientifically trained in medicine, thoroughly aware of his personal obligations to his patients and capable not only of treating sickness but also of teaching people how to keep well.

As the result of educational campaigns and propaganda we of the medical profession have created in the public a health consciousness that has made it thoroughly alive to the importance of preventing disease as well as curing it. Today the people expect something more of their doctor than mere care during illness, they require someone competent to advise and direct them in all matters pertaining to their health. In short, the general practitioner of the future must be a "health adviser" as well as a physician. With the control of the great epidemic diseases and other advances in preventive medicine the span of life has been steadily increased, with the result that where once the acute infections played a dominant rôle as a destructive factor now the degenerative diseases incident to advancing years and the wear and tear of life have become the most important causes of disabling illness. Consequently, the "man in the street" who is well aware of these changed conditions, is now chiefly concerned in how to escape cancer, how to avoid becoming a diabetic, how to maintain his kidney function, and how to prevent premature occlusion of his coronary or cerebral circulation and other similar questions. It is upon such pertinent health problems as these that he wants and will in time demand sound medical advice and periodic physical examinations. To meet this need the family health adviser of tomorrow must be alive to the requirements of preventive medicine as applied to the individual. He must be prepared to fill satisfactorily the deficiencies along these lines that unfortunately have existed in the past.

So complex and important have the various methods of diagnosis become that it will never be possible for any individual to become proficient in all branches. Therefore, specialists will always be necessary and, as medicine advances, complicated technical procedures will always be required. In order, however, to have all the studies that may be necessary for any given patient properly correlated and evaluated, there should be some one responsible individual capable of acting as a coordinator. This again is obviously the function of the properly trained modern family doctor. In the future, therefore, a definite move should be made to place the general practitioners in a central position among their professional colleagues.

When a new school of medical practitioners shall have been developed and when such practitioners have firmly reestablished themselves in the minds of the people as their proper health advisers, another important step looking toward protection of the public will take place. As people have sought less and less the guidance of competent general physicians they have acquired more and more the habit of self medication and have fallen victim to the high pressure salesmanship of the drug manufacturers, chain stores, proprietary medicine vendors and a host of other commercialized forms of

advice relative to all varieties of human ills. Fostered by radio broadcasting, popular magazine articles, quasi-scientific lectures and literature and other forms of insidious and alluring advertising, this evil has grown to an enormous extent. It is unnecessary to dwell upon the obvious dangers to health that are brought about by this unintelligent attitude on the part of a thoroughly exploited public. All this has been and is being constantly and admirably done by our national medical society that spares no effort to protect our people. Repeated investigations have shown that each year the American public not only jeopardize themselves but bear an unwarranted economic burden in the vast sums of money which they expend on proprietary remedies and self medication. When this tendency shall have been checked another enormous reduction in the cost of medical care will have been affected. In bringing this about there is no one in such an advantageous position as the modern family physician—an added argument in favor of reeducating the people to look upon such physicians as their legitimate and reliable guides and mentors in all matters pertaining to their well-being.

The members of this College, interested as they must be in the improvement of medical education and the advance of clinical medicine, can do much to further the development of the general practitioner of the future who shall combine the functions of "health adviser" with that of director and coordinator of the medical activities of the people. If in the future, men who embody the qualifications referred to can become the guiding figures in the medical life of our communities, the needs of the public will be adequately cared for and many of the most debated problems of medical economics will be automatically solved.

The modernizing of the family doctor with its attendant curbing of specialization and the inevitable lowering of the cost of medical care, will go a long way toward regaining the confidence of the public in the medical profession. The doctor will be returned to that position of respect, trust and affection which he should occupy in the hearts of the people and, like his predecessors, he will again become an outstanding figure and leader in the affairs of his community and the progress of this nation.

A turning point has come in American medicine. We stand at the crossroads eagerly searching for the guide who can extricate us from the by-ways of uncertainty and point out the highway of progress along which medicine of the future should advance.

The time is at hand when we must look to the more effective control of specialization in medicine, a movement in which the American College of Physicians is bound to play a leading part. Adverse criticism has been directed against the lack of proper regulation of specialization. Control in the sharply differentiated fields of medical practice, such as eye, ear, nose, throat and other specialties, offers little difficulty. The problem becomes more complicated, however, when we attempt to apply it to the broad field

of internal medicine. The solution for the internist may rest in limiting recognition to the subdivisions of internal medicine, as cardiology, gastroenterology, etc.

Your Board of Regents, cognizant of this development, is already active in setting up educational requirements that will be sufficient to guarantee in the future the ability of all successful candidates for Associateship in this College to qualify as internists.

Although the College has made great strides it is destined to further achievements. This is assured by the enthusiasm, ability and distinction of those in whose hands its future rests.

In conclusion, let me again express to you my sincere thanks and appreciation for the honor which you conferred upon me when you saw fit to elevate me to the presidency of the American College of Physicians.

INHIBITORY HORMONES AND THE PRINCIPLE OF INVERSE RESPONSE

By J B COLLIP, F A C P, *Montreal, Canada*

It has been a matter of great interest to those working in endocrinology to note in the case of many laboratory animals and also in the case of many patients, that a state of lowered reactivity, of increased resistance or of actual non-responsiveness may gradually become manifested in those that have been treated for a long period with some glandular extract. Likewise, it has been observed that certain previously untreated animals or patients may be non-responsive to injections of a known potent glandular extract. We have only to think of the failure of the parathyroid hormone to affect appreciably the blood serum calcium of the rabbit or of the patient who is resistant to enormous doses of thyroid extract.

In the extensive study that has been made in our laboratory during the past two years upon the thyreotropic hormone of the anterior pituitary, it was proved abundantly that animals treated for some weeks with this hormone extract became non-reactive to it. Moreover, it was shown that the injection of the blood serum of such non-reactive animals into normal animals caused these latter also to become non-reactive to administered potent thyreotropic extracts. The production of a serum inhibitory to the thyreotropic hormone therefore became a possibility. Extending our study, it was found that such an inhibitory principle could be demonstrated in the blood of the rat, rabbit, dog, goat and horse after treatment for six weeks or longer with adequate amounts of the thyreotropic extract.

Further evidence both of a direct and an indirect character has been obtained which would tend to show that inhibitory substances for various hormones may appear in the blood of animals treated for long periods with different hormone extracts. Thus hypophysectomized rats have become non-responsive to the purified growth hormone (Q extract) in about 40 days. Rats which have been treated with the ovary stimulating placental hormone for long periods, and in which the ovaries have become non-responsive, still respond to the maturity factor contained in anterior pituitary. Likewise, rats rendered non-responsive to the maturity factor of anterior pituitary still respond to placental hormone.

The serum of animals treated for many weeks with the placental hormone has been shown to inhibit the effect of placental extract in the immature female test object.

The serum of a horse treated for three months with the pituitary growth hormone has been shown to antagonize the effect of growth hormone on the hypophysectomized rat.

* Read at the Chicago meeting of the American College of Physicians April 17, 1934
From the Department of Biochemistry McGill University, Montreal, Canada

We have obtained most positive evidence of the presence in the serum of horses treated with certain pituitary extracts of substances inhibitory to the ketogenic effect of anterior pituitary extracts

It is not my purpose in this communication to discuss the details of the experimental evidence which has been obtained to support the theory that inhibitory hormones are produced as a response on the part of the organism to the introduction of excessive amounts of various hormones. I wish rather to enlarge upon the theory itself

The production of serum inhibitory to a specific hormone may be viewed in one of two ways. Either the administered hormone extract is acting as an antigen and the inhibitory substance which can be detected in the blood serum of the treated animal is an antibody, or else the inhibitory substance represents a normal constituent of the blood which under normal conditions is balanced, as it were, against the respective hormone in such a manner as to be masked itself. We prefer this latter view, that the inhibitory substance which is found in the blood of animals after prolonged treatment with some hormone extract is a normal constituent of blood. The response of the organism to chronic injections of hormone would consist then in the increased production of the respective inhibitory principle. This theory may be extended further and one may suppose that for each hormone, or at least for many hormones, there exists an opposite, an anti- or inhibitory principle

We have adopted as a working hypothesis the view that anti-hormones, perhaps better called inhibitory principles, are present in the normal subject. This broad principle is particularly attractive since it may be used to explain such things as the great difference in the responsiveness of different species to hormones as well as minor variations in responsiveness within a species. The theory is not without attraction from the clinical side, since it suggests the possibility that any supposedly hypo-hormone state may just as well be a hyper-inhibitory hormone condition or an imbalance between the hormone and its respective inhibitory principle. If one pictures a hormone and its respective inhibitory principle as a complex and views this complex as a "buffer," then one can introduce a quantitative factor in relation to the level of this complex and one species of animal can be sought in which the "buffer" is normally at a low level and others will be found in which the "buffer" is at a much higher level.

In view of the fact that there are many examples of extreme variation in the response of an individual of one species to administered hormone as compared to the response of an individual of another species similarly treated, I was led to postulate in my Welch lecture¹ a few weeks ago, the theory of inverse response.

The principle of this theory can be illustrated by a specific example.

The pituitary of the guinea pig as compared with that of the rat contains relatively very little of the thyreotropic principle, the thyroid of the guinea pig as compared with that of the rat is relatively inactive, the metabolism

of the guinea pig is at a lower level than that of the rat, the guinea pig is exceedingly sensitive to administered thyreotropic hormone, while the rat is extremely resistant. However, the hypophysectomized rat is exceedingly sensitive to this hormone.

The principle of inverse response of which the above is an excellent example may be stated as follows:

“The responsiveness of an individual to administered hormone varies inversely with the hormone content or production of the individual's own gland.”

It is possible to find numerous examples which indicate the very general application of this principle in endocrinology, and as an independent theory it can stand alone. We have been interested, however, in linking the theory of inverse response with the theory of anti-hormones. If one does this then one of the most important implications of the theory is that the level of a hormone is related directly to the level of the corresponding anti- or inhibitory hormone. The demonstration of a hyper-hormone state associated with lowered responsiveness to administered hormone implies the co-existence of a hyper-inhibitory hormone state. One might here draw an analogy between the highly buffered solution which is sluggish in regard to pH change on addition of small amounts of acid or alkali and the hormone resistant animal which is, as it were, well buffered by a high level both of hormone and respective inhibitory principle in its system.

That the effect of a small dose of a hormone will be greater when the existing concentrations of hormone and anti-hormone circulating are small than when they are already large will not be regarded as surprising. In many cases of physiological antagonism between drugs, it is known that the *ratio* between the concentrations of the two antagonists determines the physiological effect, whatever the actual amounts, this has been shown for the interaction of atropine and pilocarpine on salivary secretion,² of atropine and acetyl choline on the frog ventricle,^{3,4} of adrenalin and ergotamine on the rabbit uterus,⁵ and elsewhere. The *ratio* will obviously be more disturbed by a given *amount* of hormone when the quantities of hormone and anti-hormone present are initially small.

CLINICAL APPLICATIONS

The clear-cut demonstration of the production of inhibitory substances in the serum of animals for certain hormones with which the experimental animals have been treated should provide occasion for the serious consideration of those effects of a similar nature which may be produced in patients injected with certain glandular extracts over a long period of time. One sees, for instance, the possibility of the clinician in his endeavor to correct a hypoglandular state actually adding to the gravity of the condition by causing an overproduction of inhibitory principle as a result of too persistent treatment.

While the results of these recent investigations in the laboratory suggest that many dangers may attend the clinical use of glandular extracts, nevertheless they point the way to new applications. If the general principles established by the experimental work are applicable to the human subject, then the possibility must be considered of producing inhibitory hormones in an active way in the system of the patient, or of raising the level of these in a passive way by the use of active extracts of inhibitory sera, the latter produced from horses injected over long periods with adequate amounts of the purified hormones.

LYMPHOSARCOMA AND HODGKIN'S DISEASE BIOLOGIC CHARACTERISTICS *

By SOLOMON GINSBURG, M D , *New York, N Y*

FOR more than half a century after Hodgkin¹ first described the disease that now bears his name, no sharp line of demarcation was drawn between lymphosarcoma and Hodgkin's disease. Indeed, the two names were considered synonymous by the overwhelming majority of competent investigators of this baffling problem².

In 1893 Kundrat of Vienna recorded a study of 50 cases of lymphosarcoma in which the following tissues and organs were involved: lymph glands, skin, subcutaneous tissues, muscles, breasts, bones, dura, tongue, palate, pharynx, tonsils, larynx, trachea, bronchi, lungs, pleura, thyroid, thymus, pericardium, vena cava, esophagus, stomach, duodenum, jejunum, ileum, cecum, rectum, peritoneum, mesentery, and omentum.

Based principally upon a gross anatomic study of these 50 cases and 100 allied cases, Kundrat³ sought sharply to differentiate lymphosarcoma from Hodgkin's disease on the following grounds:

| <i>Lymphosarcoma</i> | <i>Hodgkin's Disease</i> |
|---|--|
| 1 Invades the capsule of lymph glands | 1 Does not invade the capsule of lymph glands |
| 2 Invades and infiltrates neighboring tissues | 2 Does not invade or infiltrate neighboring tissues |
| 3 Obliterates normal structure of the lymph glands | 3 Does not obliterate normal structures of the glands |
| 4 Extension regional, from one group of lymph glands to another or from one lymphoid area to another. Metastases by way of the blood stream are absent or very rare | 4 A systemic disease from the outset like leukemia |
| 5 Infiltration of hollow viscera by direct extension from involved lymph glands or involved lymphatic channels | 5 Involvement of viscera through blood or lymph channels by the unknown agent of the disease |
| 6 Invasion of hollow viscera causes dilatation of lumen, never constriction | 6 Involvement of hollow viscera causes constriction of lumen |
| 7 Rarely invades bone | 7 Frequently invades bone |
| 8 Invasion of liver and spleen nodular | 8 Invasion of liver and spleen diffuse |
| 9 Persons between the ages of 25 to 55 most frequently affected | 9 Younger individuals more frequently affected |
| 10 Male sex twice as frequently affected as females | 10 Female sex more frequently affected |
| 11 Tuberculosis of the lungs rarely present | 11 Tuberculosis of the lungs frequently present |

The histological description of lymphosarcoma given by Kundrat was limited to the following single paragraph: "As to the histological structure, I have nothing new to add. Lymphosarcomas are characterized by their

* Received for publication April 4, 1934

From the Radiotherapy Department and the Surgical Service, Cancer Division, Montefiore Hospital, New York, N Y

reticular stroma and embedded lymphoid cells. It must be emphasized that the lymphosarcomatous tissue does not resemble normal reticular lymphoid tissue. The typical or normal tissue is replaced by atypical stroma with a variable amount of fibrosis and hypertrophy and hyperplasia of cells which deviate from the normal type."

A careful analysis of this histological description probably explains the reason why Kundrat failed sharply to differentiate lymphosarcoma from Hodgkin's disease on the basis of microscopic structure as he did on gross anatomic considerations. A comprehensive survey of the literature until the time of Kundrat's publication fails to reveal in the great majority of outstanding studies on lymphosarcoma and Hodgkin's disease any distinctive microscopic features by means of which these two diseases could be sharply differentiated from one another.

A definite microscopic differentiation of lymphosarcoma from Hodgkin's disease, which occasionally was met with in the literature, was first strongly emphasized shortly after Kundrat's publication by Paltauf² of Vienna, and within the next few years it reached its finished form in the writings of Carl Sternberg⁴ of Vienna and of Dorothy Reed⁵ of Baltimore.

Based upon a careful microscopic study of 15 cases clinically diagnosed pseudoleukemia or Hodgkin's disease, Sternberg formulated the following differential diagnostic points between lymphosarcoma and Hodgkin's disease.

| <i>Lymphosarcoma</i> | <i>Hodgkin's Disease</i> |
|---|---|
| 1 Invades capsule of lymph gland | 1 Does not invade capsule of lymph gland |
| 2 Invades neighboring tissues | 2 Does not invade neighboring tissues |
| 3 Abundance of atypical lymphoid cells No endothelial hyperplasia | 3 Abundance of large endothelioid cells with an admixture of lymphoid and plasma cells |
| 4 Characteristic uninuclear and multinuclear giant cells absent | 4 Characteristic uninuclear and multinuclear giant cells always present |
| 5 Absence of giant cells and endothelioid cells in the blood and lymph sinuses | 5 Presence of large number of giant cells and endothelioid cells in the blood and lymph sinuses |
| 6 Absence of Langhans giant cells | 6 Presence of Langhans giant cells |
| 7 Absence of caseation necrosis | 7 Frequent presence of caseation necrosis |
| 8 Tubercle bacilli absent | 8 Tubercle bacilli frequently present |

The differential diagnostic features between lymphosarcoma and Hodgkin's disease drawn by the Viennese pathologists gained immediate acceptance in the scientific medical world. The only phase that met with prompt dissent by a number of competent students of this problem was the rôle of the tubercle bacillus in the etiology of Hodgkin's disease. One of the foremost among these dissenters was Dorothy Reed of Baltimore, whose classical description of Hodgkin's disease has received widespread and well-merited recognition in the English speaking world.

Accepting in the main Sternberg's histologic description of Hodgkin's disease and stressing in addition the frequent presence of eosinophiles, Reed correctly pointed out that Langhans giant cells, caseation necrosis and tubercle bacilli are an associated condition in Hodgkin's disease and not a part of the disease. In a series of eight cases clinically diagnosed Hodgkin's

disease at The Johns Hopkins Hospital a careful histological study during life revealed the characteristic pathological histology of Hodgkin's disease. In none of the specimens studied were the histological features of tuberculosis revealed or tubercle bacilli detected. In one of the cases that came to autopsy an associated miliary tuberculosis was discovered, which was interpreted as a terminal infection.

Based upon her own studies and a review of the literature, Reed agreed with the Viennese pathologists that Hodgkin's disease was purely an inflammatory granulomatous process but entirely rejected the tubercle bacillus as the underlying cause of the disease for the following reasons:

| <i>Tuberculosis</i> | <i>Hodgkin's Disease</i> |
|---|--|
| 1 Necrosis and caseation are the rule | 1 Necrosis and caseation are rare unless secondary infection occurs |
| 2 Invades and breaks through the capsule of the gland | 2 Does not invade and break through the capsule of the gland |
| 3 Shows miliary tubercles or general inflammatory changes with typical caseation, Langhans giant cells and tubercle bacilli | 3 Shows typical non-tuberculous histology unless complicated by tuberculosis as a secondary phenomenon |

When tuberculosis occurs in Hodgkin's disease, Reed concluded, it is always a distinct pathological condition and may be present either as (a) a concomitant condition in different organs, (b) an associated condition in the same organs or tissues affected by Hodgkin's disease, or (c) a terminal condition in the course of the disease.

Thirty-one years have now elapsed since Reed's classical description of Hodgkin's disease. During these years a voluminous literature has sprung up dealing with the various phases of lymphosarcoma and Hodgkin's disease. With few exceptions, the overwhelming majority of investigators have embraced the viewpoint of the Viennese pathologists that a sharp line of demarcation exists between lymphosarcoma and Hodgkin's disease. Lymphosarcoma is regarded as a frankly neoplastic disease while Hodgkin's disease is looked upon as a purely inflammatory granulomatous process—a lymphogranuloma.

Among the first clear dissenting voices sharply disagreeing with the views of the majority were those of Benda⁶ and Chian⁷ and Yamasaki.⁸ In a small series of cases of typical Hodgkin's disease observed by them, careful morphological studies revealed invasion of the capsule of the glands and of the veins. The chief biologic characteristics which distinguish a malignant neoplasm from a benign growth, namely, invasive growth into the neighboring tissues and vascular channels, were found by them to be present not only in lymphosarcoma but also in Hodgkin's disease. The most important differential points which Kunderat had stressed between lymphosarcoma and Hodgkin's disease were thus proved to be untenable. Nor did their studies corroborate the views of Sternberg that Hodgkin's disease is merely an atypical form of tuberculosis masquerading in the guise of pseudoleukemia. The tubercle bacillus was entirely excluded as a causative

factor in the group of cases of Hodgkin's disease studied by them histologically and bacteriologically

In 1906 Gibbons⁸ of San Francisco published a careful morphological study of nine cases of classical Hodgkin's disease. These strikingly brought to view the incorrectness of Kundiat, Paltauf and Steinberg's differential criteria between lymphosarcoma and Hodgkin's disease. In Gibbons' cases the capsule of the gland was invaded, the neighboring tissues were invaded and infiltrated, the normal structure of the gland was obliterated, the mode of extension was regional and metastatic-hematogenous, the invasion of liver and spleen was definitely nodular, eight of the nine patients were adults and all of them males. In no case was tuberculosis found as an associated condition.

Gibbons was especially impressed by the invasion of blood vessels and the hematogenous mode of dissemination of the proliferating cells. Contrary to the belief which still prevails today among many eminent pathologists that Hodgkin's disease develops only in areas of preexisting lymphoid tissue by the invasion of the unknown infectious agent of the disease, Gibbons noted that the specific lesions in the viscera seem to originate in the vicinity of blood vessels. In one of the cases "in which the lung was affected, the metastases showed plainly that they were not alone developments of preexisting lymphoid tissue in the organ, but progressed as true malignant metastases by pushing the tumor structure already formed into adjacent tissues, destroying them, and occupying their places, while large nodular metastases occurred in the lower lobe removed from the invading part of the tumor and not in the vicinity of the bronchi—that is in a situation where no lymphoid tissue exists normally."

Having been thus impressed by the gross anatomic malignant characteristics of Hodgkin's disease, which fully paralleled those of lymphosarcoma, Gibbons carefully reviewed the morphological-histological reasons that have induced many pathologists then—as well as now—to declare Hodgkin's disease a non-neoplastic inflammatory granulomatous infectious disease. These reasons dogmatically given then as now are. In neoplastic growth it is only one type of cell which shows the proliferative growth, while in granulomatous proliferation many cells participate in the process. In lymphosarcoma the growth is composed entirely of atypical lymphocytes, hence it is a true neoplasm, while in Hodgkin's disease there is a polymorphous proliferation of endothelioid cells, lymphocytes, fibroblasts, eosinophiles, giant cells, polynuclear cells, plasma cells and mast cells.

Gibbons' conclusion was that morphologically also there is no fundamental distinction between Hodgkin's disease and lymphosarcoma. Histologically, he found that the pathological tissue in Hodgkin's disease is composed of a proliferation of cells of the germinal centers of the gland, the endothelium lining the sinuses, the reticulum cells of the connective tissue, capsule and blood vessels. The proliferation may go on simultaneously from the three sources or one may outstrip the others. *If it goes on with*

the same tempo in all the three tissues the morphological picture is that of classical Hodgkin's disease, if one cell type outstrips the others we have more in the foreground the sarcomatous nature of the process The correctness of this viewpoint is attested by the transition stages of affected glands in which even the staunch supporters of the inflammatory granulomatous nature of Hodgkin's disease find it difficult or impossible to differentiate it from sarcoma and have therefore suggested a Hodgkin's type of sarcoma⁹ Clinically, biologically, and morphologically Gibbons concluded, Hodgkin's disease and lymphosarcoma are not sharply demarcated diseases but merely variations of the same malignant neoplastic process, namely, lymphosarcomatosis

One year later, in 1907, Coley¹⁰ stated "My own conclusion, based upon a study of upwards of 600 cases of sarcoma, 76 originating in the lymph glands of the neck, is that Hodgkin's disease is merely a variety of sarcoma, maintaining as a rule a fairly definite clinical and pathological type, but yet, in many cases, shading off into other types that correspond most closely with the ordinary types of round cell sarcoma If the malignant nature of the disease becomes generally accepted, as I believe it undoubtedly will, it will be hard to find a better name for the disease than lymphosarcoma or lymphosarcomatosis"

In 1908 further studies by Coley¹¹ and Dietrich¹² stressed the local invasive character of Hodgkin's disease and its frequent invasion of veins, hence favoring hematogenous dissemination Nevertheless, the sharp line of demarcation between lymphosarcoma and Hodgkin's disease was stoutly maintained in the standard textbooks and monographs dealing with Hodgkin's disease, and, even in the two outstanding comprehensive studies on Hodgkin's disease by Fabian¹³ and Ziegler¹⁴ published in 1911, in spite of a wealth of evidence in favor of the close clinical, biological, and morphological relationship between Hodgkin's disease and lymphosarcoma, their fundamental difference was strongly upheld This nearly universal viewpoint was disturbed in 1911 by only one dissenting case report by the veteran pathologist Chiari,¹⁵ who recorded the autopsy findings in a case clinically and microscopically diagnosed Hodgkin's disease The findings showed compression of the esophagus, invasion of lungs and pericardium, and discrete nodules in the spleen Microscopically, the normal architecture of the lymph glands was gone The capsule was invaded, the fat and bronchi were infiltrated, and the veins and arteries were definitely invaded A search for tubercle bacilli and Fraenkel and Much¹⁶ organisms proved negative

In 1913 Oliver¹⁷ published a study of 22 cases of lymphosarcoma, 11 cases of Hodgkin's disease and 13 cases of endothelioma of lymph nodes His conclusions are Hodgkin's disease must be classed with lymphosarcoma and endothelioma of lymph glands as a neoplastic process for the following reasons

1 The similarity, and in certain cases the identity, of the histologic process

2 The early and constant invasion of the capsule and veins

3 The ultimate formation of true metastases, partly at least through the blood stream

In none of the cases of Hodgkin's disease studied by Oliver was there any histological evidence of the presence of tuberculosis or of the Fraenkel and Much organism

In 1914 it appeared as though at last the true nature of Hodgkin's disease as a mere variation of lymphosarcoma was gaining recognition among the official teachers of pathologic histology. For, that year marked the publication of "The Principles of Pathologic Histology" by Dr. Frank Mallory,¹⁸ an outstanding student of morphological histology, who classed Hodgkin's disease among the frankly neoplastic diseases as a lymphoblastoma, a mere variation of lymphosarcoma. Indeed, he overreached himself when he designated Hodgkin's disease as scirrhus lymphoblastoma, for certainly Hodgkin's disease during its early evolution has a phase as highly cellular as lymphosarcoma. On the other hand, lymphosarcoma, as stressed by Kundrat³ in his original paper on lymphosarcomatosis, presents during the course of its evolution a scirrhus stage, phase, or variety as in Hodgkin's disease.

Was it overemphasis of the late degenerative or regressive phase or stage of Hodgkin's disease and the slighting of the early highly cellular polymorphous phase of the disease which accounts for Mallory's failure to make sufficient impression upon the profession? Or, was it the apparently ultra-radical view—a view already suggested by Banti¹⁰ in 1903—which would embrace in one group Hodgkin's disease, lymphosarcoma and lymphatic leukemia—which made Mallory's classification unacceptable to the majority of pathologists who are strong adherents of static morphological histology? Whatever the explanation is, the fact remains that Mallory's views found very limited acceptance among pathologists outside the Harvard group.

In 1915 one of the early students of our problem, Dr. William B. Coley,²⁰ published a comprehensive monograph on "Primary Neoplasms of the Lymphatic Glands Including Hodgkin's Disease." His vast experience and further studies since his first publications on the disease had thoroughly impressed upon him the common nature of lymphosarcoma and Hodgkin's disease. "In one of my cases," he states, "a tumor of the axillary glands was pronounced in the original report, lymphosarcoma, and the same pathologist described it two years later as an endothelioma. Other specimens were pronounced round-celled sarcoma by one pathologist and Hodgkin's disease by another. This is common observation." The same year Bloomfield²¹ reviewed the bacteriological evidence produced by Fraenkel and Much,¹⁹ de Negri and Mieremet,²² Bunting and Yates,²³ and others pur-

porting to show that Hodgkin's disease is an infectious disease caused by diphtheroid organisms His conclusions were

- 1 Organisms can frequently be cultivated *intra vitam* from diseased as well as from apparently normal glands

- 2 There is a higher proportion of successful cultures from definitely diseased glands than from those apparently in a normal condition

- 3 None of the 29 strains isolated in the author's series of cases could be shown to be the cause of specific disease

- 4 Pleomorphic diphtheroid organisms were isolated not only in a few cases of Hodgkin's disease but also in lymphosarcoma, carcinoma, arthritis and other conditions

- 5 Injections of diphtheroid organisms into a monkey failed to produce any definite lesions

- 6 Autogenous vaccine therapy given in two cases of Hodgkin's disease and in three cases of infectious arthritis failed to produce any results

One year later, 1916, Ghon and Roman²⁴ published a comprehensive study on lymphosarcoma based upon an extensive review of the literature and a thorough histological study of 31 cases They draw a sharp distinction between Hodgkin's disease, which they consider as a lymphogranuloma, and lymphosarcomatosis, which they regard as a frankly neoplastic disease They state that clinically and gross-anatomically the two diseases cannot always be differentiated One wonders, however, how can such differentiation always be made even on the basis of histological morphology in the light of their verified observation "In lymphosarcoma we find fairly represented all the cellular elements of lymphadenoid tissue lymphoblasts, lymphocytes, macrophages, plasma cells, and even giant cells"

Perhaps even more important than this observation of the presence of polymorphism of cells in lymphosarcoma as in Hodgkin's disease was their observation of the frequent invasion of blood vessels by the lymphosarcomatous growths and their tendency to hematogenous metastases, as in Hodgkin's disease Kundrat's original claim that hematogenous metastases in lymphosarcoma are absent or very rare and that extension of the disease is from one group of lymph nodes to another or from one lymphoid area to another—a belief still widely held today by many clinicians and pathologists—was entirely disproved by Ghon and Roman's thorough and careful histological observations A detailed study of the mode of dissemination of lymphosarcoma in 27 out of their 31 cases revealed

- 1 Direct extension and metastases to regional lymph nodes in six cases

- 2 Direct extension and metastases to regional and distant lymph nodes in four cases

- 3 Lymphogenous and possibly hematogenous metastases in five cases

- 4 Local lymphogenous and hematogenous metastases in 12 cases

Two years later Warfield and Kristjanson²⁵ reported a case which on first admission to hospital gave the distinctive pathologic picture of lympho-

sarcoma Upon readmission the blood picture was that of acute lymphatic leukemia, while glands removed from the axilla just before death showed a picture indistinguishable from typical Hodgkin's disease

In 1917 Cunningham²⁶ again reviewed the status of diphtheroids with special reference to Hodgkin's disease and produced proof that the diphtheroid organism in a series of cases of Hodgkin's disease was a mere laboratory contamination and could not be obtained in typical cases of Hodgkin's disease when careful bacteriological methods were used to prevent contamination

In 1921 Mueller²⁷ published a study of 16 cases of Hodgkin's disease In two of the cases the disease exhibited "a change in the histological structure from typical lymphosarcoma to round-celled sarcoma or vice versa In one of the two cases the disease exhibited malignant neoplastic properties with invasion of lungs, aortic wall, and spinal canal" From a morphologic-histological point of view," Mueller concluded, "the opinion seems justified that lymphosarcoma and round-celled sarcoma of the lymph-nodes are only different expressions of the same process"

In 1925 another one of Kundrat's differential diagnostic dogmas between lymphosarcoma and Hodgkin's disease was completely disproved by Liu²⁸ of Pekin, China In a study of 12 cases of lymphosarcoma of the small intestine from the pathological department of The Johns Hopkins Hospital, Baltimore, Liu found stenosis of the gut in 10 of the cases Kundrat's original observation of the presence of dilatation in lymphosarcomatous tumors of hollow viscera—which led him to the hasty generalization that invasion of hollow viscera by lymphosarcoma causes dilatation of lumen, never constriction—was thus proved untenable, and once again the danger of generalizing from a comparatively small number of cases was emphasized

One of the most instructive cases of Hodgkin's disease showing its close relationship, if not identity, with lymphosarcoma was published by McCartney²⁹ in 1928 A woman of 52 developed progressive loss of weight, pallor and dyspnea, followed one year later by enlargement of the cervical lymph glands A biopsy of one of these glands was reported small round-celled sarcoma Several months later, in 1927, nodes removed from the neck and axilla were reported lymphatic leukemia The patient died in March 1928 Autopsy revealed invasion of lymph glands, skin, lungs, liver, and kidneys by nodular growths

Microscopic examination showed "In one lymph node four distinct histologic types are present In some areas one sees the typical picture of Hodgkin's disease with Dorothy Reed type of cell In other areas the appearance is that of lymphatic leukemia In many places there are numerous spaces lined by an endothelial type of cell, giving an appearance simulating closely but not quite duplicating that of primary endothelioma of lymph nodes Finally certain areas show a large type of cell with marked

evidence of active growth, with numerous mitotic figures and a small amount of reticulum, an appearance commonly called lymphosarcoma. Scattered through the node are microscopic areas of necrosis and marked fibrosis." The involved visceral organs showed similar histological pictures.

The same year, 1928, Coley³⁰ reported a new series of 58 cases of lymphosarcoma and 39 cases of Hodgkin's disease. He reiterates "For many years I have held that these two conditions, which are usually regarded as quite different and distinct, are actually quite closely allied etiologically, and bear such a close resemblance to one another that in some instances it is impossible to differentiate them either clinically or histologically."

Further recent studies entirely in agreement with the view that Hodgkin's disease and lymphosarcoma are merely variations of the same malignant neoplastic process were recorded by Letulle, Tremolières and Moussour,³¹ Callender,³² Warthin,³³ Levin,³⁴ Wellbrock and Lougherty,³⁵ and others.

My own observations and studies during the past 13 years, based upon more than 100 cases of Hodgkin's disease and lymphosarcoma, are entirely in agreement with the viewpoint that biologically, clinically, and morphologically they are merely variations of the same disease. To justify this viewpoint, in the course of our study, abundant detailed evidence will be submitted, of which the following two case reports will serve as introductory illustrative examples.

CASE I

Mrs. V. G., aged 54, was admitted to the Montefiore Hospital on September 13, 1929, complaining of pain in the right shoulder, a lump in the right axilla, progressive weakness, and loss of weight. Duration of symptoms, seven months.

In February 1929, without any apparent predisposing or exciting causes, she developed pain in the right shoulder. A few weeks later she discovered a painless lump in the right axilla. Prompt medical consultation resulted in a diagnosis of tumor of the right axillary lymph glands and operation was advised. A resection of the tumor was done on April 28, 1929, by a prominent New York surgeon, who found the mass "composed of glands of various sizes. Some were quite hard and felt like carcinoma, others were much softer and had the appearance of sarcoma." The pathologist's report was typical Hodgkin's disease.

One week after the operation the patient developed an acute chest condition which was diagnosed as pneumonia. The respiratory symptoms subsided within a few weeks but her general health showed progressive deterioration. She became very asthenic and partly bed-ridden.

On admission to the Montefiore Hospital on September 13, 1929, she looked pale and emaciated. The mouth showed a few remaining carious teeth and no other abnormality. There were many stony hard and matted together lymph nodes in both cervical regions. There was a scar in the right axilla and no recurrence of any tumor mass. The lungs showed slight dullness at apices and bases. The heart showed no abnormalities. The liver was palpable about 5 cm. below the costal margin. The spleen and kidneys were not palpable. There was a median ventral hernia. The rectal and vaginal examinations were negative.

Radiographic examination of the chest on September 20, 1929, revealed normal lungs and mediastinum and moderate left ventricular enlargement.

Blood examination showed hemoglobin 90 per cent, white blood cells 10,000, polynuclear leukocytes 78 per cent, lymphocytes 20 per cent, eosinophiles 2 per cent. The blood Wassermann was negative. Urinalysis was essentially negative.

Course under Roentgen Therapy Following deep roentgen display to the cervical lymph nodes the masses decreased in size but the patient's general condition gradually grew worse. Reexamination on January 12, 1930, found her complaining of profound weakness and a completely bed-ridden state, dryness of the throat, cough and expectoration, profuse night sweats, pain in the right upper posterior chest, pain in both arms and in the lumbosacral spine. She looked paler than on admission. The following superficial lymph glands were found to be enlarged: right pre-auricular, left cervical, left axillary, right epitrochlear, and left inguinal. The right breast was enlarged and markedly edematous. The skin over it had a typical pig-skin appearance. The lungs and heart did not show any gross abnormality. The abdomen failed to reveal any tumor masses. The spleen was not palpable. The liver was felt 5 cm below the costal margin. The lower extremities showed slight edema.

On February 23, 1930, a hard immovable, circumscribed, tender mass measuring 5 by 5 by 3 cm was noted over the upper sternal region and contiguous chest wall. The mass felt bony-hard in consistency and seemed to be fused with the ribs and sternum. At this time a radiographic examination of the chest revealed an area of consolidation in the right lower lobe. It also showed a slight thickening of the periosteum along the anterior surface of the first portion of the sternum. There was a partial collapse of the body of the seventh dorsal vertebra to about half its size.

The predominant clinical symptoms were toxic and respiratory. She ran a remittent febrile course with temperatures to 103°. A blood count, done on March 18, 1930, showed 3,600,000 red blood cells, 75 per cent hemoglobin and 8,600 white blood cells. The polynuclear leukocytes were 86 per cent, lymphocytes 8 per cent, monos 4 per cent, eosinophiles 1 per cent, and basophiles 1 per cent.

Cautious deep roentgen-ray therapy was applied to the chest lesions with little effect upon the course and development of her illness. She steadily went down hill and died from toxemia and respiratory embarrassment on September 27, 1930.

Necropsy revealed (1) Hodgkin's disease involving the cervical, mediastinal, periaortic, retroperitoneal, mesenteric, peri-pancreatic and iliac lymph nodes, the thyroid, right breast, both lungs, right bronchial tree, spleen, pancreas, stomach, jejunum, cervix, vagina, bladder and vertebral bone marrow.

2 Bilateral hydronephrosis

3 Chronic purulent cholecystitis, cholangitis and cholelithiasis with stones in the hepatic duct and in the papilla of Vater

4 Ulceration of the neck of the gall-bladder

5 Extreme fatty metamorphosis of the liver

Detailed Study of the Hodgkin's Lesions *Skin and Breast* Above the right breast and extending into the axilla is a 16 cm old scar. The right breast is about twice the size of the left. The skin is thickened and wrinkled and shows two fairly punched-out ulcerations. There is considerable edema of the right arm. Over the skin of the chest the infiltration is rather hemorrhagic in character. On section, the right breast shows a plum-sized mass of exceptional firmness, homogenous, grayish in appearance, rather gristly in texture from which strands of similar tissue are seen to extend crab-like through the adipose tissue and into the underlying tissue. The pectoral muscles are almost completely absorbed and the fascia above the thorax is markedly infiltrated by this firm, gray tissue. Microscopically the lesion presents the typical picture of Hodgkin's disease. The wall of one of the veins and its vasa vasorum show invasion (figures 1 and 2).

Bones Four contiguous lumbar vertebrae examined reveal diffuse replacement of red marrow by a yellowish, homogeneous, firm tissue.

Neck Organs The cervical lymph nodes are enlarged and on section show a similar firm homogeneous tissue. There is a small, circumscribed, whitish-gray nodule in the right lobe of the thyroid. Microscopically the nodule, apparently a lymph node,

FIG 1 (Case I) Diffuse invasion and infiltration of Hodgkin's disease in the wall of a breast vein. Suspicion of invasion of vasa vasorum

FIG 2 Invasion of vasa vasorum by Hodgkin's reticulum and giant cells

entirely replaced by Hodgkin's tissue, is seen to infiltrate the capsule and invade the thyroid (figure 3)

Trachea and Bronchi The mucosa of the trachea is slightly injected. Beginning just above the bifurcation there is a marked alteration of the mucosa of the bronchus

FIG 3 (Case I) Invasion of thyroid by Hodgkin's disease

which is considerably thickened, very irregular and apparently replaced by a similar very firm, homogeneous, grayish tissue. The change extends into the smaller ramifications of the bronchi to both upper and lower lobes. Tracheo-bronchial lymph nodes are enlarged and very firm. On section they are markedly degenerated but are definitely invaded by a similar tissue.

Lungs The right lung feels heavy and there is a peculiar sensation on palpation due to scattered areas of almost wooden consistency throughout the entire lung. Posteriorly and over the anterior surface of the upper lobe there is complete obliteration of the pleural cavity. The remaining surface of the lung has a mottled emphysematous and congested appearance. The lung is very pale. Occasionally one sees beneath the pleura a circumscribed, very small raised nodule composed of a

homogeneous grayish tissue On section there is an astounding picture The upper lobe is almost entirely replaced by exceedingly firm, raised, pigmented, homogeneous, grayish tissue which is very sharply defined from the pale and somewhat edematous normal lung These nodules, varying in size from an orange to a plum, constitute about three-quarters of the upper lobe The lower lobe is fairly well aerated, pale in color Scattered throughout are small circumscribed nodules of a similar, very firm, grayish, slightly pigmented tissue The parietal pericardium is firmly adherent to the mesial surface of the right lung

Microscopical Examination Many of the alveoli are filled with fibrinous material and serum In the interstitial tissue and extending into the alveoli are typical Hodgkin's tissue, Dorothy Reed giant cells, occasional lymphocytes and areas of fibrosis and necrosis

The mediastinal lymph nodes are markedly enlarged Microscopical examination shows typical Hodgkin's

Heart Extreme fibrosis Marked calcification of the coronaries

Abdomen The peritoneal cavity is free from fluid The mesentery is atrophic and contains numerous enlarged and discrete lymph nodes which on section contain a very firm grayish tissue from which no juice can be scraped Some of these nodules show a considerable amount of pseudo-mucin

Spleen Slightly enlarged Weighs 210 gm Measures 12 by 8 by 5 cm The capsule is smooth, slightly wrinkled and reddish-gray in appearance Notches are well preserved On section the pulp has a fleshy, rather homogeneous appearance, and yields little on scraping Trabeculations are quite marked Near one blood vessel is an almost wedge-shaped area made up of very firm grayish tissue At the lower pole there is replacement of the pulp over an area the size of a cherry by a very firm, glistening, grayish tissue Microscopic examination reveals large areas of necrosis and hemorrhage with areas of fibrotic Hodgkin's tissue The uninvolved portion of the spleen shows atrophy of pulp tissue with very small follicles

Stomach and Jejunum On the anterior wall of the stomach in the fundus, are two circumscribed, dime-sized ulcerations of the mucosa with fairly thickened walls Numerous enlarged nodes are present along the attachment of the mesentery to the peritoneal surfaces of the small and large intestines In the mid-portion of the jejunum there is an ulceration of the mucosa about 4 by 1.5 cm whose long diameter is perpendicular to the direction of the intestines The edges of the ulceration are very firm and are raised On the serosal surface are several small collections of firm, grayish tissue which are in relation with a very large node in the mesentery near by Microscopically the mucosa and submucosa are infiltrated with typical Hodgkin's tissue

Gall-Bladder and Liver Free from any neoplastic tissue on gross and microscopical examination

Pancreas A small area at the head of the pancreas containing compressed but relatively normal tissue is all that remains of the normal pancreas The remainder, including the body and tail and a portion of the head, is replaced by a very firm, homogeneous, rather gristly tissue in which are a few yellowish areas (figure 4) This infiltration of the pancreas causes a threefold increase in the size of the involved portion Numerous lymph nodes in this region at the head of the pancreas and along the greater and lesser curvature of the stomach are replaced by similar tissue

Suprarenals Normal in size and shape and free from tumor tissue

Kidneys Free from tumor Both pelves and ureters are slightly dilated The terminal thirds of both ureters are in close relation to and compressed by a chain of enlarged lymph nodes extending from the bifurcation of the aorta along the iliacs to the femoral region

Iliac Vessels Are firmly ensheathed in a large group of lymph nodes

FIG 4 (Case I) Invasion of pancreas by Hodgkin's disease

FIG 5 (Case I) Invasion of uterus by Hodgkin's disease

Fig 6 (Case I) Invasion of bladder by Hodgkin's disease

Ovaries Fallopian tubes and rectum are free from tumor

Uterus The upper right fundal portion of the uterus is replaced by a homogeneous yellowish-gray appearing tissue which is confined entirely to the muscular coat (figure 5) The cervix is markedly enlarged and on section contains similar tissue

Vagina The upper portion of the vagina shows numerous serpiginous ulcerations, and submucosal thickenings caused by growth of similar very firm tissue

Bladder Grossly no evidence of tumor growth Microscopically the wall of the bladder is infiltrated by Hodgkin's tissue (figure 6)

CASE II

Mrs M H, aged 61, journalist, was admitted to the Hospital on February 21, 1924

Chief Complaints Pain in upper abdomen, left lower posterior chest, left lumbar and lower sacral regions, paraplegia, parasthesia of lower extremities, tumor mass over hip, marked weakness and loss in weight Duration of symptoms, 14 months

Present Illness On January 1, 1923, without any apparent predisposing or exciting causes, while stooping forward to lace her shoes she was seized with a violent twisting pain in the left upper abdomen, recurring several times during the day and lasting each time a few minutes The next day she consulted a local physician who diagnosed visceroptosis and advised the wearing of an abdominal belt The belt was promptly donned and gradual subsidence of pain in the abdomen followed Shortly thereafter she experienced a dull aching pain in the left lower lateral chest She immediately consulted another local physician who discovered an enlarged spleen and had her blood examined Internal medication was prescribed with gradual relief of the pain in the chest In February she began to have drawing and twisting deep-seated pain in the upper mid-abdomen sharply localized and non-radiating The pain was constant and severe but was not accompanied by any other local or constitutional symptoms In May she consulted another local physician who diagnosed myalgia and myositis and prescribed a liniment and internal medication In June she began to have very severe pain in the lower part of the spine aggravated on motion She was forced to spend most of the time in bed to obtain partial relief from pain

In July her daughter, while giving her a rub-down with alcohol for the sore lower spine, discovered a mass the size of a hen's egg over the right hip The mass was neither painful nor tender and according to the patient's observation had apparently not undergone any change in size until admission to Montefiore Hospital some six months later

In August she was taken to a large hospital in New York where her spine was radiographed and pronounced negative The presence of the lump over the right hip apparently elicited no comment or attention and she was discharged with a diagnosis of lumbago

Gradually the pain in the lower spine increased in severity, disability became more marked and she became almost completely bed-ridden

In November she consulted a gynecologist for cystocele which she herself had noticed a year before and which she now suspected as the possible cause of her severe and disabling backache The presence of cystocele was confirmed and at her own request a pessary was inserted The gynecologist, however, did not feel quite convinced that the cystocele was the sole cause of the underlying complaints and advised orthopedic consultation This was promptly agreed to She was examined by an experienced orthopedist who ordered a brace for supposed spondylitis Unfortunately, however, neither brace nor pessary produced any relief from the severe backache and within a few days after their application she developed prickling and numbness in the soles of both feet gradually extending upward to the hypogastrium and associated with weakness of both lower extremities

In December the pessary was removed but the paraplegia became more pronounced and she was unable to sit up in bed

In January 1924, she was admitted to a hospital in New York where her case was diagnosed as postero-lateral sclerosis of the lower lumbar cord possibly due to tumor. The presence of a tumor over the right hip and invasion of the lungs by neoplasm were also noted but their exact interrelationship was not understood. The patient was given a series of intramuscular injections without the slightest benefit and on February 21, 1924, nearly 14 months after the onset of her first complaints, she was admitted to the neurological service of Dr. Philip S. Goodhart at the Montefiore Hospital.

Examination revealed an old pale-looking and emaciated woman presenting no cachexia, dyspnea or cyanosis. The skull and scalp were negative. The teeth were almost all gone, only a few badly carious ones remained. The tongue was heavily coated and tremulous and the left half was atrophic. The tonsils were small and buried behind the pillars. The pharynx was free from any neoplastic disease. The neck showed no enlargement of lymph nodes. The thyroid gland was not palpable.

Chest and Lungs Diminished vocal fremitus and dullness from the top of the right scapula to the base. A few slightly enlarged lymph nodes were palpable in the left axilla, none in the right.

Heart Negative

Abdomen Distended, tympanitic. On deep palpation a diffuse doughy mass can be felt along the midline. The liver is palpable 4 cm. below the costal margin, the surface is smooth, the edge sharp. The upper level of liver dullness extends to the fifth intercostal space. The spleen is palpable 1 cm. below the costal margin. The iliac, inguinal and femoral lymph nodes are greatly enlarged, discrete, non-tender, varying in size from $\frac{1}{2}$ to 2 to 3 cm. Over the left gluteal region a mass the size of a hen's egg, soft, non-tender and freely movable, is present.

Rectal and Vaginal Examination Negative

Neurological examination reveals involvement of the twelfth cranial nerve evidenced by slight fibrillary tremor affecting the whole tongue and atrophy of its left half. There is definite paraplegia. A sensory belt of hyperesthesia begins about two inches above and ends about two inches below the umbilicus. Below this belt there is hypesthesia. Very little motion is possible in the lower extremities. The patient can just lift her knee off the bed but cannot maintain it in that position. There is a bilateral Babinski and markedly exaggerated knee jerks.

Laboratory Data Radiographic examination of the chest shows a dense homogeneous shadow extending from the right apex to the base. Blood examination moderate secondary anemia. White blood cells 11,200, polynuclears 74 per cent, small lymphocytes 9 per cent, large lymphocytes 6 per cent, mononuclears 6 per cent, mast cells 2 per cent, eosinophiles 2 per cent. Urine analysis practically negative. Biopsy of lymph node shows large reticulum cell lymphosarcoma.

Course under Roentgen Therapy Following deep roentgen therapy to the lower spine and chest there was slight recession in symptoms. The further clinical course of the disease was mainly characterized by further generalization of the neoplastic process, progressive wasting, persistent toxemia and terminal pneumonia superimposed upon the neoplastic lung involvement.

Necropsy revealed generalized lymphosarcoma with involvement of mediastinal, retroperitoneal, iliac and inguinal lymph glands, thyroid, sternum, pleura, lungs, heart, peritoneum, small intestines, adrenals, liver and kidney.

Detailed Autopsy Report The body is that of an elderly, slenderly built, markedly emaciated female, 150 cm. long.

Scalp, brain, pituitary and pineal negative.

Eyes, ears and nose negative.

Mouth Mucous membranes pale

Teeth Many missing, remainder well kept

Tongue Negative

Tonsils Small, pitted, scarred

Larynx and Trachea Normal

Neck Negative except for a few shotty glands on both sides along the lateral borders of the sterno-mastoid

Thyroid Both lobes slightly larger than average, the right hard though smooth. There is an elongated nodule of apparently normal thyroid on the right side of the midline separate and distinct from the right thyroid lobe which measures 1.5 by 0.5 by 0.3 cm. On section, the greater portion of the right lobe with the exception of the upper pole is replaced by smooth grayish white tissue in the center of which is a small area of calcification. The left lobe contains an ill defined nodule 1.5 cm in diameter in its upper pole, the remainder of the lobe is apparently normal and colloid containing. Microscopic examination shows isolation and replacement of thyroid follicles by tumor throughout.

Parathyroids Normal

Upper Extremities Negative

Chest Breasts atrophic. Slightly to the left of the midline in the region of the third and fourth ribs is a bulgy, firm tumor mass about 7 cm in diameter, over which the skin is freely movable. The mass is seen to infiltrate the elevated intercostal muscles and the medial portions of the pectoral muscles. The removal of the sternum and costal cartilages is accomplished with difficulty because of extensive tumor involvement of the mediastinum and the anterior surface of the pericardial sac.

Pericardial Sac There is a wide layer of tumor tissue externally which binds the pericardial sac to the medial surface of both lungs. On opening the pericardial sac, both the visceral and parietal surfaces are covered with a shaggy fibrinous layer and in the parietal pericardium are numerous flattened grayish white tumor nodules, discrete and confluent, measuring up to 2 cm in diameter and 5 mm thick.

Heart Weighs approximately 200 gm. The entire visceral pericardium is covered with shaggy fibrinous exudate. On section the heart muscle is decidedly brown and injected. No abnormalities are found in the endocardium or valves. *Microscopic* Muscle fibers are thinned out, the vessels slightly thickened. An organizing fibrinous layer is found on the epicardial surface. In the edematous epicardium is a small tumor area.

Right Pleural Cavity Is completely obliterated in its upper two-thirds, in its lower third it is filled with a hemorrhagic fluid containing large fibrin masses. The parietal and visceral pleura all over is markedly thickened and in the region of the diaphragm measures 5 mm.

Right Lung The two upper lobes are air-containing throughout. The lower lobe is markedly collapsed, atelectatic. On section, both upper lobes are markedly edematous and slightly congested, the lower lobe collapsed and dry. The tumor tissue in the visceral pleura measures up to 7 mm in thickness along the diaphragmatic and visceral borders. The bronchi are slightly dilated. The larger arteries are slightly but distinctly thickened throughout. The root glands are enlarged, grayish white, firm.

Left Pleural Cavity Contains about 700 c.c. of clear straw colored fluid and a few dense fibrous adhesions at the apex of the upper lobe and over the posterior surfaces of both lobes. There are numerous small tumor nodules on the parietal pleura.

Left Lung Both lobes are fairly well collapsed. A few fibrous tags are present on the parietal surfaces. There is a healed scarred area at the apex of the upper lobe. Scattered throughout the visceral pleura of both lobes are flattened nodules.

up to 1 cm in diameter and 3 mm thick. On section, both lobes are moderately congested and edematous. The bronchi are dilated, the vessels normal. The root glands are markedly enlarged and at the hilum they surround the larger bronchi and appear underneath the mucous membrane. *Microscopic* Extensive replacement and diffuse tumor infiltration of lungs with areas of necrosis and fibrosis.

Abdomen Spleen small and free from tumor.

Liver Weight 880 gm. Small, soft. Capsule thin. On the inferior surface are numerous small nodules up to 1 cm in diameter, 3 mm thick. On section, tissue greasy brown, lobulations fairly regular, numerous tumor nodules up to 5 mm in diameter are seen and a single large nodule 2 cm in diameter. Microscopic examination reveals invasion of veins by tumor cells.

Esophagus and Stomach Negative for tumor.

Duodenum There is an elevated nodule 7 mm in diameter and 2 mm thick, immediately anterior to the ampulla. The remainder of the duodenum is negative.

Jejunum and Ileum At irregular intervals are numerous, slightly flattened, nodular, grayish white and injected tumor nodules in the mucous membrane, measuring from 3 to 7 mm in diameter and 2 to 4 mm thick. These nodules are numerous in the jejunum and do not infiltrate the muscle layers.

Pancreas Free from tumor.

Appendix Coiled up in a mass of adhesions though on section the lumen is patent throughout.

Cecum Except for a nodule of tumor tissue on its peritoneal surface in the region of the adhesions described, no abnormalities are seen. Microscopically tumor tissue infiltrates the muscle layers and the peritoneal coverings of the cecum and appendix.

Colon No abnormalities.

Suprarenals The right suprarenal weighs 5.5 gm and is of average size and consistency. On section, the cortical tissue is narrow and fatty, and the medulla is softened. The left weighs approximately the same and is for the most part adherent to the tumor tissue on its posterior surface. On section, the cortical tissue is fatty, the medulla is prominent, and there is a small tumor nodule 5 mm in diameter in the medulla.

Kidneys Each weighs 110 gm and is of average size and consistency.

Right Capsule slightly diffusely adherent and in places firmly adherent to large tumor nodules. The nodules appear on the surface as slightly elevated, grayish white nodular areas up to 2 cm in diameter and slightly umbilicated. The remainder of the surface shows marked superficial pitting. On section, there is slight congestion throughout. The tumor nodules are seen to replace large portions of the cortex and pyramids, but in places the architecture is still retained. The striations are regular and prominent. At the hilum the tumor tissue is seen surrounding but not occluding the larger vessels. Pelvis and ureter negative.

Left Contains small tumor nodules but is otherwise similar to the right. The large arteries are markedly thickened.

Ovaries, tubes, vagina, and bladder are free from tumor.

Microscopic The tumor consists of fairly uniformly sized, small polygonal cells with irregular nuclei, the latter are in instances pale staining, and occasionally multilobulated. There are a moderate number of mitotic figures, rarely a syncytial giant cell. In places the cells are small and round, resembling lymphocytes.

COMMENT

A parallel study of the above two cases reveals the following very instructive facts:

- 1 Both were females past middle life.
- 2 In neither case was there any predisposing or exciting cause to explain the etiology of the disease.

3 In neither case was tuberculosis found on postmortem examination

4 Invasion of the capsule of lymph glands and invasion and infiltration of neighboring tissues occurred in the Hodgkin's case no less than in the lymphosarcomatous case

5 Obliteration of the structure of glands occurred just as freely in the one as in the other

6 Extension in the Hodgkin's as well as in the lymphosarcoma case was regionally invasive and metastatic through lymph and blood channels. Invasion of veins and hematogenous mode of systemic dissemination were demonstrated in both

7 Infiltration of hollow viscera did not differ from metastatic invasion in epithelial cancerous growths

8 In both cases bone was invaded

9 The lesions in both were predominantly nodular or diffusely infiltrative in different tissues and organs

10 Both diseases, although widely generalized, were, on gross and microscopic study limited to about the same number of organs and tissues, as follows

Lymphosarcoma Case

Lymph glands, thyroid, bone, pleura, lungs, heart, peritoneum, small intestine, cecum, appendix, adrenals, liver, kidney

Hodgkin's Case

Lymph glands, thyroid, skin, bone, breast, lungs, bronchi, spleen, pancreas, stomach, jejunum, uterus, vagina, bladder

11 Necrosis and hemorrhage occurred in lesions of both types. Though fibrosis was more marked in the case of Hodgkin's disease the clinical course of the disease was not materially altered thereby

12 Both ran a mild remittent fever

13 Eosinophilia in the blood was absent in both

14 Toxemia and cachexia were more marked in the case of lymphosarcoma than in that of Hodgkin's disease

15 Both died from toxemia and pulmonary involvement without any marked compression of mediastinal structures

16 The clinical duration of life was 24 months in the lymphosarcoma case as against only 20 months in the Hodgkin's case

Biologically, therefore, Hodgkin's disease varies in no fundamental characteristic from lymphosarcoma. Whatever variations it may present at times are merely variations that one would expect to find in any disease affecting different individuals under different constitutional and environmental conditions

THE ENCEPHALITIS EPIDEMIC IN ST. LOUIS¹

By DAVID P BARR, M D , F A C P , *St Louis, Missouri*

DURING the summer and autumn of 1933, 1097 cases of epidemic encephalitis were reported in St Louis and in St Louis County¹ Study of the disease has revealed that it differs in many important respects from the encephalitis lethargica of von Economo and that it is not definitely identifiable with the Japanese Encephalitis B Although it has previously attracted little attention, it may not be entirely new in this country In 1932 cases of a similar condition were seen in the small city of Paris, Illinois, where in a population of 9000, 27 cases were reported^{2,3}

Due to a most effective organization of the Health Department of St Louis and to admirable cooperation between local and Federal agencies, unusual opportunities were afforded for study of the entire epidemic⁴ Over 90 per cent of the reported cases were treated in hospitals where clinical records are readily available The correlation of these data has been placed in the hands of a committee which is representative of the many agencies involved in the work and which will soon publish a comprehensive monograph Although the report of the committee will furnish an authoritative and detailed analysis of the clinical and laboratory observations, it does not seem inappropriate that a brief outline should be presented before the College of Physicians at this time, more particularly since outbreaks of a similar character and of greater or less severity may possibly occur in other communities during next July, August and September

The summer of 1933 in St Louis was unusually hot and dry June was the hottest ever recorded After heavy spring rains there was a prolonged drought and in June, July and August the rainfall was the lowest in the history of the city Conditions of drainage were favorable to the breeding of extraordinary numbers of mosquitoes

It is now known that a case of encephalitis was seen as early as July 7 and that several isolated cases were observed in St Louis County during that month A state of epidemic became dramatically apparent on August 8, when the City Isolation Hospital received from the county 16 cases of an unusual type of encephalitis Others rapidly followed Since such an experience was entirely new in this country it is not surprising that much confusion in diagnosis occurred Because of the severe headaches and high fever, the not infrequent bradycardia and leukopenia, typhoid was often suspected It is interesting that requests for Widal tests from the health department were 100 per cent higher than in a similar period of the previous year In some cases the chill of onset led to a suspicion of malaria Signs of meningeal irritation with increased mononuclear cell count in the spinal

fluid suggested even to experts the probability of tuberculous meningitis. When from pathological studies encephalitis was demonstrated, it was naturally assumed that the disease was encephalitis lethargica in an atypical form and that it would be followed by the usual distressing residuals. The well justified fear of encephalitis lethargica and its consequences no doubt contributed to the widespread attention given to an epidemic which, although serious, involved only about one in one thousand of the population in a limited area.¹

CLINICAL FEATURES

Clinical study of the disease has revealed a striking similarity in the symptoms of individual patients with modifications referable in large part to the intensity of infection, the localization of lesions, to age and previous physical and mental constitution^{5, 6, 7}. A typical case of maximum severity may be cited.

A white woman of 53 left her home on the morning of September 6 apparently in good health. While working she was suddenly seized with severe headache and vomiting. She soon became delirious and on the following day was somnolent. On September 9 when she was brought to Isolation Hospital she was stuporous, her temperature was 105°, and her pulse rate was 154. The conjunctivae were injected. There was moderate injection of the naso-pharynx, a marked rigidity of the neck, a gross tremor of the lips and tongue, absent abdominal reflexes, exaggerated deep reflexes, positive bilateral Kernig and extensor response to plantar stroking of both great toes. The white blood cell count was 10,200. The spinal fluid was under increased pressure, gave a positive Pandy test and contained 82.0 mg per cent of sugar. There were 200 cells per cu mm with 90 per cent of lymphocytes. The urine contained albumin, red blood cells, white blood cells and casts. Two days later she died with a temperature of 107.4°.

A milder case and one more representative of the disease as it occurred in children was seen in a colored boy of six. On August 27 he was seized with headache and vomiting followed by drowsiness and pain on bending his neck. Two days later he entered the Isolation Hospital, where examination revealed a temperature of 103°, an injected pharynx, a tremor of the tongue, slight rigidity of the neck, and diminished deep reflexes. There were no pathological toe signs and the abdominal reflexes were present. The white blood cell count was 9400. The urine was normal. The spinal fluid was under moderately increased pressure and contained 130 cells, 91 per cent of which were lymphocytes. The Pandy test was negative. Sugar, as determined by the Benedict method, was present in the fluid. His temperature fell by lysis and in three days was normal. He was discharged on September 21 without symptoms or signs of disease.

An extremely mild case observed by Dr. T. C. Hempelmann may also be cited. This was a 19 year old girl who, although she had had headache, photophobia, a sensation of fever for a period of six days, had not been

confined to bed. At the time of entrance to the hospital she was found to have 107 cells in her spinal fluid. Five days later and on the eleventh day of her disease she felt entirely well and wished to go home.

The purposes of this paper permit no extensive analysis of symptoms. In about half the cases the onset of the disease was sudden, often with a chill or with vomiting, occasionally with convulsions, which were seen in adults as well as in children. In other patients there seemed to be a period of invasion for three or four days with fever, headache, general pains, photophobia and conjunctivitis and slight rigidity of the back and neck. At the end of this prodromal period a sharp rise in temperature was common and the subsequent course was similar to the cases of more abrupt onset.

Although several patients revealed no fever during the period of observation, the usual temperature at the height of the disease was 103 to 104°, in occasional cases rising to 106°. The pulse was usually proportional to the temperature but bradycardia was not infrequent and tachycardia was observed in some of the more severe cases.

Headache, stiff neck, and a positive Kernig sign were relatively constant symptoms. Although diplopia or blurring of vision was noted in many, strabismus, ptosis, and facial weakness were relatively uncommon, occurred early and were usually transient. The abdominal reflexes, which varied greatly with the stage of the disease, were often absent during acute severe illness. The deep reflexes varied too greatly to be of diagnostic importance. Pathological toe signs were not infrequently encountered.

Coarse tremors of the hands and arms often increased by intention and gross tremors of the tongue were seen in many cases. The speech was uncertain and tremulous. Although many patients appeared somnolent or even stuporous, they could usually be aroused sufficiently to answer questions. In a few cases delirium and sleeplessness were prominent features.

The white blood cell count usually ranged from 10,000 to 14,000 with extremes from 2800 to 36,000. During the acute stage the Schilling differential revealed a moderate infectious picture but was not sufficiently characteristic to serve as an aid in diagnosis or prognosis.

The spinal fluid during the acute stage was often under increased pressure. In the majority of instances 100 to 300 cells were recorded but this was subject to considerable variation and in one fluid 1100 cells were found. Lymphocytes usually predominated, although at times polynuclear cells constituted from 30 to 50 per cent of the total. It is important to note that in some cases the fluid withdrawn on the first spinal puncture was normal while a second puncture a day or two later revealed the characteristic increase in cell count. Of diagnostic significance were the sugar determinations which by the Shaffer-Hartmann method varied from 20 to 146 mg per cent, in the great majority of cases being well above the range seen in tuberculous meningitis.

The urine, often normal, showed in many instances albumin and casts,

but in amounts not greater than those encountered in other acute infections. In a few cases changes indicative of extensive renal damage were found.

A relatively short course was characteristic of the disease. The fever usually remained high from three to five days, and then gradually fell, reaching normal in 7 to 10 days after the onset. A critical drop in temperature, however, was not uncommon. Somnolence or stupor persisted during the febrile course. The cell count in the spinal fluid often remained high after all subjective symptoms had disappeared and in some cases was still elevated three weeks after the onset when the patient was discharged from the hospital.

PROGNOSIS

Among 1059 cases there were 221 deaths, a mortality of almost exactly 20 per cent¹. The prognosis was not clearly dependent upon the degree of meningeal involvement, the height of the initial temperature or the number of cells in the spinal fluid. The age of the afflicted individual was of the greatest importance, the mortality being less than 5 per cent in patients under 40 and approximately 50 per cent in those over 60. Most of the deaths were attributable in part to complications, by far the most

FIG 1 Incidence and Mortality Rate at Various Ages
(Data from the St. Louis Health Department¹)

frequent of which was pneumonia. Previously existing nephritis, hypertension and arteriosclerosis seemed to play an important rôle. Several patients who had not been previously recognized as nephritics died in uremia. Not more than 10 per cent of the deaths could be attributed to uncomplicated encephalitis.

Although serious residual manifestations were uncommon, some degree of disability was apparent in many patients at the time they were discharged from the hospital. In December, approximately three months after the subsidence of the epidemic, an examination was made of 375 of the 447 surviving patients in the City of St. Louis. Of these, 133 revealed no residual symptoms. One patient had remained in a state of delirium. Another was subject to convulsions. Paralyzes or localized weakness of muscles were seen in 21. Personality changes such as excitability, melancholy or sullenness were found in 45. Forgetfulness or confusion, usually slight, was not uncommon. Tremor of some degree was still apparent in 72 patients. The most usual complaints were of headache and general pains. Sleeplessness, weakness and fatigue were also frequently mentioned. While this survey has shown that complete recovery occurred after three months in less than half the cases, it is fair to say that most of the changes were slight and that few were disabling. Especially encouraging is the fact that no new symptoms of encephalitis had developed and that there was no single instance of progression of the disease.

PATHOLOGY

The pathological lesions, although sufficiently distinctive to establish a diagnosis of encephalitis, did not serve to differentiate sharply the cases of the St. Louis epidemic from those of encephalitis lethargica. Possibly

FIG 2 Section of brain and meninges showing extensive infiltration of the meninges by cells, most of which are lymphocytes

the most notable difference was the widespread distribution of the lesions in the St Louis form of the disease. Characteristic changes⁸ were found in the meninges and throughout the brain, in the cortex, in the white substance of the hemispheres as well as in the pons and basal ganglia. They were also seen in the spinal cord. To the naked eye the most striking change was the congestion and dilatation of meningeal and intracerebral blood vessels. Capillaries were distended sufficiently to give to many parts of the brain a pinkish discoloration. The diagnosis usually depended upon (1) the intense congestion of blood vessels, (2) the infiltration of round cells about blood vessels, the so-called perivascular cuffing, and (3) the nerve cell degeneration which consisted of swelling, eccentricity of the nucleus and chromatolysis and which was usually accompanied by focal accumulation of round cells. It is of clinical interest that the nuclei of the cranial nerves were not especially involved.

In many of the fatal cases there was a hemorrhagic and edematous type of pneumonia similar to that observed in individuals dying early in the course of acute epidemic influenza. The kidneys were frequently swollen and intensely congested, with cloudy swelling of the cortex and extensive degenerative changes in the convoluted tubules. In several cases intranuclear inclusions, first noted by Dr Margaret Smith, were demonstrated in the tubular epithelium.

ETIOLOGY

The disease has been reproduced by intracerebral inoculation both in monkeys and in mice. While only about 40 per cent of monkeys are susceptible even to large inoculations, white mice may be uniformly infected by material in one-millionth dilution. Brain virus instilled intranasally in mice also has produced the disease. The lesions produced in experimental animals are consistently those observed in human cases. The investigations of Muckenfuss, Armstrong and McCordock,⁹ and of Webster and Fite¹⁰ have failed to demonstrate bacteria either in the blood or spinal fluid of patients or in the brains of experimentally infected animals. Webster has shown that the virus is filterable. Thus far 11 strains of virus transmissible to mice have been obtained in four different laboratories.

It has also been shown that the sera of patients recovered from the St Louis type of encephalitis possess neutralizing antibodies.¹⁰ Diluted virus suspended and incubated with convalescent serum does not kill mice, whereas the same virus mixed with normal serum kills regularly. To a lesser degree antibodies are present in the sera of some of the nurses and doctors who were exposed to the disease but were never ill. Neutralizing properties against the virus have also been shown in the sera of five patients who had recovered from encephalitis in Paris, Illinois, and of two patients from New York who had suffered from encephalitis thought to resemble the St Louis type.¹¹

FIG 3 Section of brain showing perivascular infiltration (cuffing) with lymphocytes

FIG 4 Higher power showing cellular infiltration about nerve cells. At the upper right there is a degenerative nerve cell in which no nucleus is visible

The contention¹² that lethargic encephalitis and the St Louis type of encephalitis are one and the same disease is fraught with many difficulties. The sudden onset, the relatively short course, the prominence and severity of meningeal symptoms, the low incidence of cranial nerve palsies and particularly the rarity of serious residual and progressive lesions are features difficult to reconcile with the clinical picture of encephalitis lethargica. Furthermore, neutralization tests have indicated that those who are suffering from lethargic encephalitis have no neutralization antibodies for the St Louis virus¹¹.

On the other hand, the clinical manifestations of the Japanese Encephalitis B are almost identical with the St Louis disease. In both there is an acute onset, high fever, meningeal as well as cerebral involvement, a short rapid course with recovery or death in a week or 10 days. In both there is a relatively low incidence of sequelae. The Japanese disease has occurred in the late summer and early fall and has carried a high mortality in older individuals. In the light of this striking similarity of clinical features, it is surprising that the sera of Japanese patients apparently do not neutralize the St Louis virus¹³.

SUMMARY

The encephalitis which occurred in St Louis in 1933 was an acute disease of relatively short duration which so far has shown little tendency to serious sequelae. Both its incidence and its mortality were greater in older people. It was caused by a filterable virus to which both monkeys and white mice are susceptible. The sera of patients who have recovered from the disease contain neutralizing antibodies. Both clinically and immunologically the St Louis epidemic differs from encephalitis lethargica. Although in its epidemiological and clinical manifestations it closely resembles the Japanese Encephalitis B, immunological reactions have indicated that the two diseases are not identical. At present it appears that the St Louis form of encephalitis has previously escaped general attention and that it is not definitely identifiable with any known condition. The circumstances of the epidemic indicate that it may appear in other communities and presumably in the summer and autumn.

CHANGES IN THE S-T SEGMENT OF THE ELECTROCARDIOGRAM IN ACUTE RHEUMATIC FEVER *

By MARY H EASBY, M D , and H ROESLER, M D , *Philadelphia, Pennsylvania*

PROLONGATION of the a-v conduction time and alterations of rhythm are the electrocardiographic changes best known to occur in the presence of acute rheumatic fever. A review of the rather scattered literature, together with our own case reports, indicates, however, that S-T (R-T) changes are not uncommon. They deserve much attention because they indicate objectively alterations of the heart musculature.

CASE I

The patient was a male, aged 25 years, who was seen first in the hospital February 14, 1933. He gave a history of rheumatic fever at seven years and of chorea at nine years of age. Six weeks previous to examination he had a recurrence of rheumatic infection followed by loss of weight, dyspnea and a left-sided paralysis of short duration. Examination revealed dyspnea, clubbing of the fingers, pallor, enlargement of the spleen and liver, one skin nodule and some glandular enlargement. There were pain and stiffness in several joints. The apex impulse of the heart had its maximum intensity in the anterior axillary line in the sixth intercostal space. A loud diastolic murmur was heard best in the third and fourth left intercostal spaces, and to the right of the sternum was heard a systolic murmur transmitted into the vessels of the neck. There was no evidence of pericarditis. The heart rate was 102 per minute and regular. The pulse was characteristic of the Corrigan type. The blood pressure was 130 systolic and 80 diastolic. The blood count showed 3,860,000 red blood cells, 10 grams of hemoglobin and 16,400 leukocytes. The Wassermann was negative. Roentgen-ray examination showed marked enlargement of the left ventricle and slight enlargement of the left auricle. There were increased pulsations of the left heart contour and aorta, and complete absence of signs of congestive lung failure.

The patient received salicylates and later a vaccine. He improved subjectively and objectively. Six weeks after admission, his red cell count had risen to 4,570,000, his hemoglobin to 13.5 grams and his white blood cells had decreased to 11,100. The pulse rate had dropped to 70. The heart findings remained unchanged. The blood pressure was 150 systolic and 20 diastolic. The patient eventually recovered from his acute rheumatic attack and was discharged from the hospital.

A series of electrocardiograms was taken during the course of this patient's illness. They showed interesting variations in the S-T segment and the T-wave, these variations being dependent apparently upon the stage of activity of the rheumatic infection.

* Received for publication February 17, 1934.

From the Departments of Medicine, Presbyterian Hospital and Temple University Hospital Philadelphia, Pa.

FIG 1 Case I

The first was taken February 14, 1933 (figure 1a) In addition to the prolonged P-R interval seen frequently in acute infections of the rheumatic type, changes are seen in the S-T (or R-T) segment and in the T-wave. These changes consist of low origin of the R-T interval in Lead I, convex upward bowing of the R-T interval, Leads I and II, late cove shape T-wave inversion, Leads I and II, and isoelectricity of T₃. The second tracing was taken March 6, 1933 (figure 1b) In Leads I and II the R-T segment takes its origin from the descending limb of R before it reaches the isoelectric line and immediately slants upward to form the T-wave. In other words, there is no isoelectric R-T segment, the T-wave apparently springing directly from the descending portion of R. The third tracing was taken two weeks later (figure 1c) The R-T segment in Lead I, and to a less extent in Lead II, has a higher origin than normal. The descending limb of R barely reaches the isoelectric line. The last tracing (figure 1d), taken two months later, shows the T-wave to be of higher amplitude. There is still no period of R-T isoelectricity, the upstroke of T originating still a little above the isoelectric line on the downstroke of R.

CASE II

The patient was a mulatto boy of 16 years, admitted to the hospital April 7, 1933, complaining of pain in his chest and abdomen. This pain was of several days' duration and had been accompanied by fever. At the time of admission the pain was of maximum severity over the precordium. His temperature was 104.6°, pulse 112, and respirations 24 on admission. The past medical history was negative except for the usual childhood diseases. No rheumatic history of any kind could be elicited.

Examination showed a pale colored boy, not dyspneic and apparently not in pain. The tongue was coated, the cervical glands were palpable and tender. No petechiae were found on either skin or mucous membranes. On the day of admission there was thought to be some impaired resonance over the left chest, and in fact, roentgen-ray examination showed some evidence of an early bronchopneumonia. These signs disappeared, however, both clinically and by roentgen-examination within a few days. The apex beat of the heart was 7 cm. outside the midsternum in the fifth interspace. There was a gallop rhythm at the apex, and over a very limited area in the third left intercostal space a systolic murmur could be heard. The rest of the physical examination was negative.

On the day following admission a very pronounced friction rub was heard over the precordium. This diminished in intensity after the first day but could be heard faintly for several weeks. The temperature came down very rapidly but there continued to be a slight afternoon rise for about two and a half weeks. Premature beats were present at times and occasionally a systolic apical murmur could be heard. Neither of these findings was constant. At no time was there any joint involvement. The patient's convalescence was for the most part uneventful and he was discharged June 25, 1933 in good condition.

His treatment was symptomatic and aimed principally at the correction of his anemia. His blood count varied from 62 per cent hemoglobin, 3,500,000 red blood cells and 16,000 white blood cells on admission, to 88 per cent hemoglobin, 4,600,000 red blood cells and 8,700 white blood cells. Other laboratory examinations gave the following results: Wassermann and Kahn, negative, blood cultures, negative, stool examination, negative, sedimentation rate one month after admission was

| | |
|------------|-------------|
| 45 minutes | 25 per cent |
| 1 hour | 36 per cent |

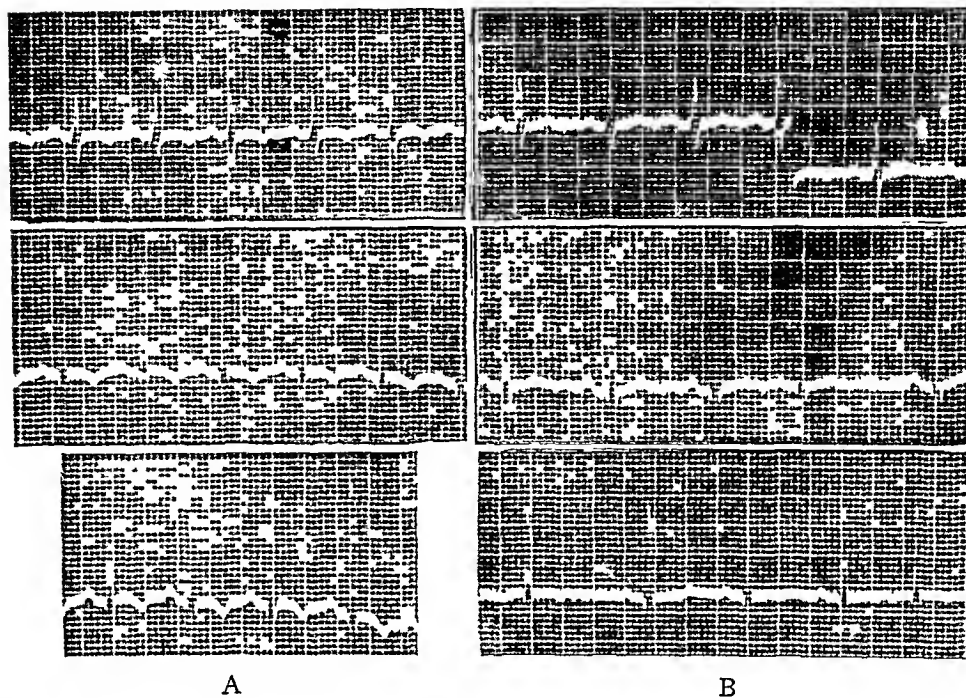

FIG 2 Case II

The test was repeated just before discharge. The results were

| | |
|------------|------------|
| 45 minutes | 4 per cent |
| 1 hour | 5 per cent |

The basal metabolic rate was plus 6 per cent. Urine examinations showed albumin and a few granular and hyaline casts at the time of admission. On discharge the urine was entirely negative. Fluoroscopic (orthodiagraphic) examination showed the cardiothoracic ratio to be 13:21 cm.

The first electrocardiogram (figure 2a) was taken April 25, 1933. It shows T-wave inversion in all three leads. The second tracing (figure 2b), taken two weeks later, shows low voltage of the T-waves in Leads I and II and isoelectricity in Lead III. Three weeks later a third tracing (figure 2c) shows an upward directed T_1 and T_2 and inverted T_3 . All the T-waves originated below the basal line, and in the second and third leads there is a deep R-T depression. Three weeks later the fourth tracing (figure 2d) shows still an upward directed but low voltage T-wave in Leads I and II and there is much less R-T depression than was seen in the earlier picture. The last tracing (figure 3) was taken about one month later.

FIG. 3. Case II

This is essentially normal except for auricular premature beats and for the fact that the R-T segment in Leads I and II arises directly from the downstroke of R without a normal isoelectric period.

CASE III

The patient was a male, aged 48 years. He was admitted to the hospital May 17, 1933, with the chief complaint of generalized joint pains and sore throat. The patient had been sick at home for three months before admission. His past history

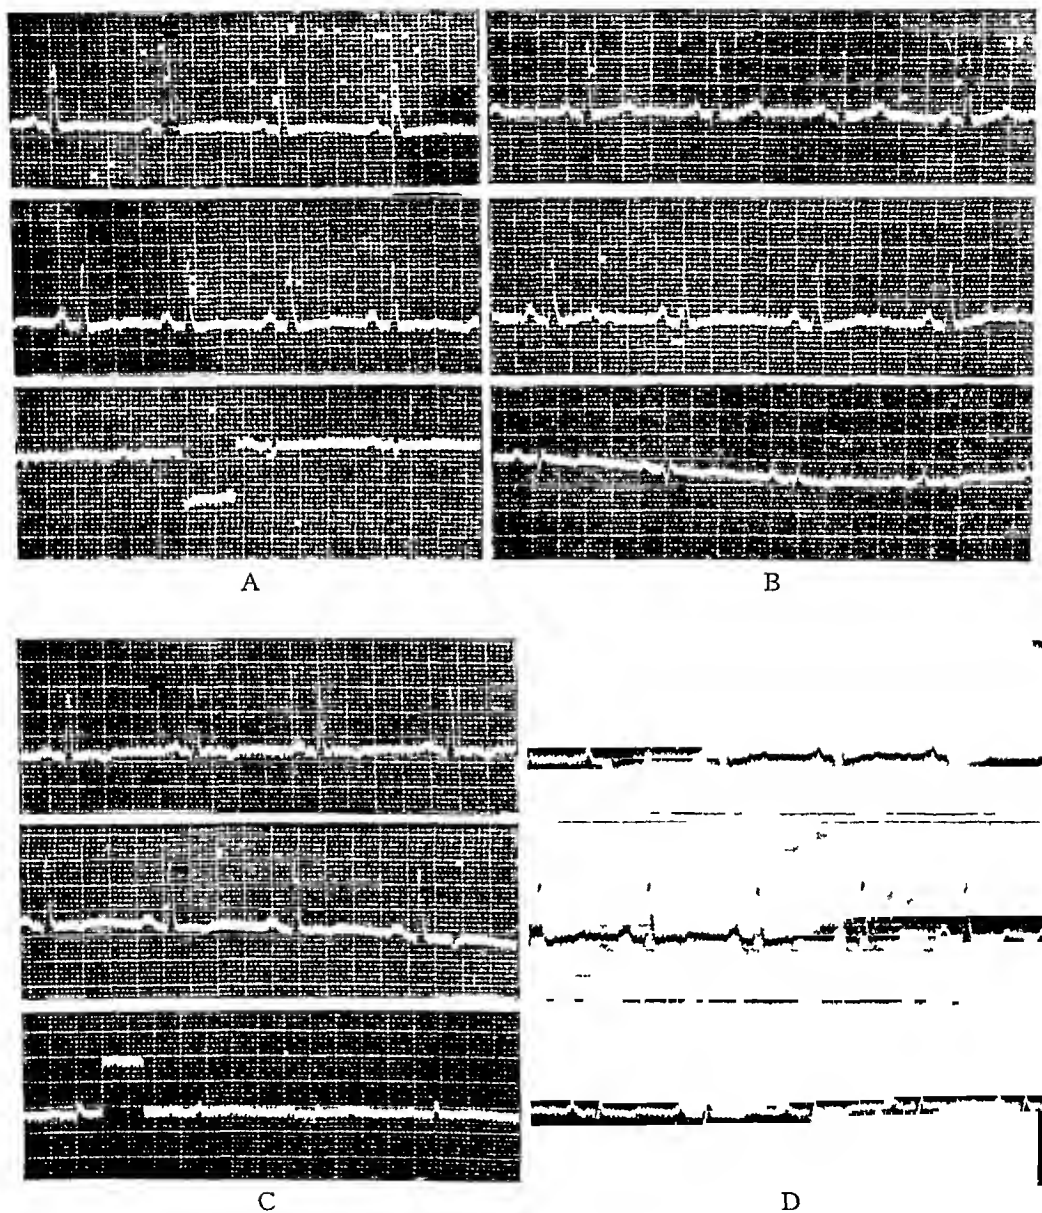

FIG 4 Case III

was negative for rheumatism but he had had scarlet fever and rather frequent sore throats in childhood. He had never had symptoms of cardiovascular disease.

On admission he was having joint pains and dyspnea. His teeth were in poor condition and his tonsils diseased. The lungs were clear. The apex beat of the heart was just outside the midclavicular line in the fifth interspace. The heart rate was 112, regular, and there was some accentuation of the second aortic sound. There

was a systolic murmur at the apex and base. The abdomen was negative. The joints of his fingers, left knee, left wrist, left elbow and shoulder were tender, swollen and hot, and there was thought to be effusion in the left knee joint. The temperature on admission was 101°.

On the day following admission, a to-and-fro friction rub was heard at the apex by one observer. This had disappeared 24 hours later and did not recur. The temperature came down to normal within about a week and the pains responded satisfactorily to salicylates. There was, however, an occasional afternoon rise of temperature of about one degree. On June 20, 1933, there was a more marked elevation for several days accompanied by the return of joint pains to a mild degree. Both fever and pain subsided after the patient was put back to bed for several days. Another rise of temperature occurred after tonsillectomy but was not in excess of what would be normally expected. There was an occasional fleeting return of joint pain, the most persistent being in one shoulder. This was effectively relieved by physiotherapy. The systolic murmur at the apex became more distinct as time went on but there was no other valvular involvement noted at any time. On admission the patient's blood count showed 73 per cent hemoglobin, 4,020,000 red blood cells and 16,250 white blood cells. One month later the count was 80 per cent hemoglobin, 4,130,000 red blood cells and 10,000 white blood cells. The urine was practically negative at all times. Sedimentation time a month after admission was

| | |
|------------|-------------|
| 45 minutes | 9 per cent |
| 1 hour | 13 per cent |

This was repeated a month later and gave practically the same results. Roentgen-ray examination showed the cardiothoracic ratio to be 17/32.5.

Electrocardiographic studies were made at intervals. The first tracings (figure 4a) were taken May 25, 1933, eight days after admission. They show a flattened T_1 , slightly inverted T_2 and an isoelectric T_3 . Three weeks later (figure 4b) the tracings show T_1 and T_2 to be upright. This was considered an improvement on the earlier ones, but on June 23, eleven days later (figure 4c) there was a distinct inversion of T_1 and T_2 . It is interesting to note that this corresponded in time to the patient's secondary rise in temperature and return of joint pain. The fourth tracing (figure 4d), taken July 16, 1933, shows a return of T-waves to isoelectricity but with a tendency for the R-T segment in Lead I to originate below the basal line on the downward limb of the R-wave.

DISCUSSION

The study of these three cases shows that in each of them the electrocardiogram has undergone changes during the course of an acute rheumatic infection. We have interested ourselves in only those changes which appear in the S-T or R-T segment or in the T-wave itself. The first case showed, during the acute infectious stage, T-wave inversion suggestive of coronary disease. This inversion showed constant improvement as the rheumatic infection cleared up, the T-wave assuming a definite upward direction. It must be noted, however, that even in the last tracing, which was taken more than two months after recovery, the T-wave arises abruptly from the downward limb of the R-wave and that there is a consequent lack of isoelectric

R-T interval The second case presents similar characteristics In the beginning there is a stage of sharp T-wave inversion, but within a period of a week or so, the T's become first isoelectric and eventually upright, although they remain of low voltage However, even in the latest tracing, in which the T-waves are upright and of satisfactory height, there is still alteration of the R-T segment The third case showed rapid improvement after the initial examination, the T-waves becoming upright and practically normal in contour in the second tracing The third tracing, however, shows definite inversion in the two first leads The patient had a reactivation of his infection at this time With his eventual complete recovery, there was still isoelectricity of the T-waves Since the R-T segment need not be absolutely flat in the electrocardiogram of normal individuals and since we have not available electrocardiographic tracings of the patients before the onset of the disease, it does not seem possible to ascribe to this finding a definite pathological significance Pardee¹ believes that rarely these alterations may be permanent, due to fibrotic changes in the myocardium, or that they may be prolonged beyond the acute manifestations of the infection, indicating possibly a continuing low grade activity A series of three cases is, of course, too small to enable one to draw conclusions regarding the frequency of these changes in rheumatic infection They afford, however, evidence confirmatory of the reports of those observers who, in the past few years, have emphasized electrocardiographic abnormalities in rheumatic infections other than the better known conduction and rhythm alterations In 1924, Cohn and Swift² reported studies on a series of 37 rheumatic patients, a number of whom showed similar R-T or S-T alterations, and they noted the similarity which some of these variations had to the type of T-wave found in recent coronary occlusion They suggested at that time that this finding indicated disturbed muscular function such as might be caused by a transient Aschoff body Bain and Hamilton³ emphasized the importance of the electrocardiogram as a means of diagnosing myocardial involvement in the course of rheumatic infections They analyzed tracings from 50 rheumatic children and found inversion of T-waves in one or more leads in eight cases, and depression of the S-T interval followed by a small T deflection in three cases They likened this finding to a "digitalis T" occurring, of course, in the absence of digitalis Rothschild, Sacks and Libman⁴ express the belief that whereas the type of change in the electrocardiogram under discussion is not pathognomonic for acute rheumatic fever, it does occur oftener in this condition than in any other single pathological state Reid and Kenway⁵ had a rather high percentage of abnormal findings in their series of 26 cases Of these, 11 showed S-T changes, and they were impressed also by the absence of S-T or R-T isoelectric periods These observers believe that there is no correlation between the duration of joint symptoms and the duration of electrocardiographic changes, and they emphasize, as do other workers, the importance of the electrocardiogram in the early diagnosis of rheumatic myocarditis McMillan

and Cook⁶ found that in 48 cases studied, 10 showed slight changes in the R-T segment and 11 showed a negative T-wave. Poite and Pardee⁷ reported on three cases with rheumatic pericarditis showing upward S-T convexity like that of a coronary thrombosis or narrowing. One of these cases at post mortem showed the left coronary artery to be thickened with an irregular subintimal proliferation. Whereas there was pericarditis present in these cases, the opinion is expressed that the abnormality in the tracings was due to inflammatory myocardial reaction, and that similar variations would appear in the absence of pericarditis.

The frequency with which pericarditis appears in the course of an acute rheumatic attack suggests the possibility that this condition in itself might be responsible for T-wave and R-T variations. Master⁸ states that the so-called coronary type of T-wave may appear in patients with rheumatic pericarditis, and furthermore that occasionally pericarditis alone may produce a flat T-wave. He cites the example of tuberculous pericarditis and cancer of the pericardium where the underlying musculature is but little involved. Cowan,⁹ however, in 1904, in a discussion of the pathological findings in the heart in acute disease, states the belief that pericarditis is a frequently unsuspected accompaniment of acute disease, and that the muscle in the vicinity of an inflamed pericardium is always degenerated. He says "As a result of pericarditis, changes may occur in the adjacent connective tissue leading to an increase in its amount, or to its degeneration, both of which necessarily cause a further defect in muscle cells." Pardee,¹ while emphasizing the daily variations in T-wave and R-T interval during the acute stage of rheumatic fever, states "A few patients, especially those with evidence of pericarditis show the peculiar upward convexity of the S-T interval followed by a downward T-wave, the 'coronary' T." The first case described in our report gave no clinical evidence of pericarditis. Of the other two, one presented the typical to-and-fro friction rub for only a very brief space of time, and at no time was there felt to be pericardial effusion in any of these patients. From a review of the literature and from our own observations we find that cases in which clinical evidence of pericarditis is lacking present T-wave alterations similar to those in which pericarditis is known to be present. Clerc, Levy and Vialard¹⁰ described isoelectricity or negativity of T-waves in 19 per cent of a series of 57 cases studied, and described one case in which the S-T interval had a high take-off in all leads. Shapiro¹¹ studied 119 cases of quiescent rheumatism in children and in adults, and concluded that changes in the S-T portion of the electrocardiogram are similar to, but of less frequent occurrence than those in active rheumatism. His control group of 50 normal cases presented only very negligible variations in repeated electrocardiographic studies. Vialard¹² found that out of 63 cases of active rheumatism studied, only 14 presented no electrocardiographic alterations and that there were T-wave changes in 18 of these cases. He did not, however, note characteristic alterations of the S-T segment other than those connected

with abnormalities of the QRS or T. He emphasized the importance of the electrocardiogram for early diagnosis of rheumatic disease, especially when its appearance is atypical such as in cases presenting pulmonary or abdominal symptoms. Vialard quotes from a French clinician, Besnier¹³ who, in 1877, wrote so significantly of the involvement of the myocardium in acute rheumatic fever, that we have felt it pertinent to present a translation of his remarks at this point. "The heart muscle is generally, one may say always, affected to some degree in the course of acute articular rheumatism. This affection may represent an advanced degree without any considerable concomitant lesion of the endocardium or pericardium. If the heart is affected by endocarditis or pericarditis then there is even much more reason to assume that the whole heart is diseased. This fact one has indeed quite forgotten and one is too much inclined to assume that all organic lesions of the heart in rheumatic disease have their origin in the endocardium and pericardium. One might call this whole condition rheumatic carditis, if this expression does not sound too antiquated."

Heiles¹⁴ definitely states that a curving of the R-T segment, either convexly or concavely, to any marked degree cannot occur in a normal heart. Having noted alterations during rheumatic infections similar to those of coronary disease, he accounts for the upward convexity or concavity on the ground of hyperfunction or hyperirritability of a portion of the ventricular muscle. He believes that if the injury to the muscle is of an inflammatory nature, the ventricular complexes will return to normal in a relatively short time. But if there is an area of necrosis such as follows an occlusion of a coronary artery, there will be a lasting dysfunction of the necrosed area. He notes that rheumatic infection is not followed by a sharp T-wave inversion coming late after the time of injury such as is caused by the scarring which follows thrombosis. Slater^{15,16} published three cases which gave the clinical signs of coronary occlusion. The first two cases showed first an elevation of the R-T interval in Leads I and II, this was followed by inversion of the T-wave, which eventually became upright again. In the third case, which had several recurrent attacks, the following changes were observed in addition: Absence of isoelectricity of the R-T segment, flattening of the T-wave, low take-off of the S-T segment in Lead II.

Sebastian¹⁷ presented a statistical study of 26 cases showing that in 15 of these cases some change in the S-T segment occurred in one or more leads, that in one or more leads a negative T-wave appeared in 11 cases, a diphasic T in seven cases, a low voltage T in 16 cases, that there was absence of T-wave in one case, that the T began above the basal line in at least one lead in four cases, and that the ascending branch of the T-wave was oblique and thickened in one or more leads in four cases. Additional statistical data on this subject are given by Lukomski¹⁸ who studied 100 cases of initial or recurrent attacks of acute rheumatic fever and who found negative T-waves in 13 of these cases. He noted that this change occurred usually at the height of the disease and that in eight of the cases the T

became positive again within 10 to 30 days. He noted furthermore the similarity of the upward directed S-T period to that caused by coronary disease but believes these changes are due to Aschoff bodies in the myocardium. Lian and Calcena¹⁹ reported that three out of 28 cases studied showed negativity of T-waves in one or more leads, but did not note alterations of the S-T interval. Master and Romanoff,²⁰ in a recent publication, reported that 53 out of a series of 63 cases of acute rheumatic fever studied, showed some variation in the RST portion of the electrocardiogram. T-wave changes occurred in 29 of these.

We are convinced from a review of the literature on this subject, as well as from our own observations, that R-T or S-T alterations of the electrocardiogram are as characteristic, though not pathognomonic, and probably of quite as frequent occurrence in acute rheumatic fever as the better known alterations in conduction and rhythm. Not only is T-wave inversion or isoelectricity of diagnostic import, but in addition the alterations in the point of T-wave origin with a consequent deformity, shortening or entire absence of an isoelectric R-T segment may be characteristic. These electrocardiographic deformities which are so similar to the deformities of coronary disease suggest that the underlying pathological processes should be looked for in the coronary circulation and a consequent interference with myocardial blood supply, a view-point which has been emphasized by Slater.^{15, 16}

The rheumatic process manifests itself in the heart as a part of a general mesenchymal disease of the organism. The course of the disease shows different stages, which later on may occur simultaneously. The first, an acute stage, is a degenerative-exudative one. It is characterized by edema and fibrinoid swelling of the matrix of the connective tissue, necrosis of muscle fibers and lymph-leukocytic infiltration is often seen. The second, a subacute stage, is often characterized by mesenchymal cell proliferation, the formation of a granuloma, though a diffuse process without this granulomatous formation may take place. The last, a chronic stage, is the process of healing with scar formation.

In this connection the pathology of only the acute and subacute stage is considered and only as far as it concerns the vessels of the heart. The affection of the aortic wall is only mentioned when coronary opening involvement is explicitly mentioned, though rheumatic aortitis (Klotz,²¹ Pappenheimer and VonGlahn,²² Breitenacker²³) may often cause coronary narrowing during the phase of exudative swelling. No mention is made of the degeneration of muscle fibers or of embolic infarction which often accompanies endocarditis (Aschoff,²⁴ Takayasu²⁵).

The following chronological survey will demonstrate, without further comment, the anatomical substratum which may be encountered during the acute and subacute stage. Needless to say, the degree of the pathologic lesions may vary enormously, and the extent of functional interference will

differ correspondingly This functional interference may find its expression in the electrocardiogram

ROMBERG ²⁶—Multiple hyaline thromboses of small arteries and veins Infiltrative periarteritis

RABÉ ²⁷—Proliferative endarteritis of small arteries, often with considerable reduction of their lumen "Mesarterite parenchymateuse"

ASCHOFF ²⁸—All coats of small and medium-sized arteries may be involved in the process of submiliary nodule formation

GEIPEL ²⁹—Rheumatic nodules occasionally narrowing the lumen of vessels Endarteritis of small and medium-sized arteries, the subendothelial fibrinous exudate narrowing or occluding the lumen of the vessels

COOMBS ^{30, 31}—Nodules in media, with unilateral narrowing of the lumen of a vessel Nodular periarteritis Inflammatory patches at the root of the aorta

KLOTZ ²¹—Periarteritis of small vessels

FAHR ³²—Invasion and semilateral destruction of vessel walls by nodules Complete degeneration in focal areas of media

WATJEN ³³—Nodular infiltration of vessel walls with thrombi in diseased vessels

COOMBS ³⁴—Turgescence of the endothelial cells of capillaries and arterioles Endothelial proliferation with disappearance of the lumen of the vessel Thromboses in capillaries, small arterioles and venules and in a main coronary artery

SWIFT ³⁵—Endarteritis with swelling and proliferation Narrowing of vessel lumen by nodules Partial or complete thrombotic occlusion

MCCALLUM ³⁶—Wall destruction of arterioles and of large coronary sinuses with thromboses

PAPPENHEIMER and VONGLAHN ²²—Inflammatory plaque in the beginning of the left coronary artery Parietal thrombus in a large coronary branch Semilateral narrowing of lumen of a vein due to subendothelial infiltration

PERRY ³⁷—Panarteritis of coronary arteries and their main branches, patchy thickening of intima, degeneration and inflammation of media, inflammatory infiltration in adventitia

KLINGE ³⁸—Marked fibrinoid swelling of the intima of small arteries and veins, with narrowing of the lumen Nodules in all wall layers of arteries and veins, intimal cushions

KLINGE and VAUBEL ³⁹—Almost complete occlusion of arteries and veins by swelling and cell proliferation of intima

BREITENECKER ²³—Intima proliferation and thrombosis occludes the right coronary opening and narrows down the left one

SUMMARY

Three cases are reported which showed during the course of a rheumatic infection the following electrocardiographic changes. First, of the S-T (R-T) segment a low or high take-off, a convex upward bowing, a depression, an absence of the isoelectric portion. Second, of the T-wave isoelectricity, low voltage, origin below the basal line, simple inversion, cove-shaped inversion. The electrocardiogram approached a normal form if the rheumatic infection cleared up but even at the stage of complete recovery there was in one case persistence of isoelectricity of the T-waves. In none of the three cases was evidence of a pericardial effusion present. These changes, though not pathognomonic for rheumatic fever, occur rather commonly, as a review of the literature shows. Anatomical studies from the literature are reported which support the conception that the S-T (R-T) and T changes express an alteration of the musculature caused by the effects of the acute infection on the coronary circulation.

THE GALACTOSE AND UROBILINOGEN TESTS IN THE DIFFERENTIAL DIAGNOSIS OF OBSTRUCTIVE AND INTRAHEPATIC JAUNDICE*

By DAVID H. ROSENBERG, M.D., *Chicago, Illinois*

THE enigma which may confront the internist in the differential diagnosis between mechanically obstructive and intrahepatic (toxic or infectious) jaundice, occurring particularly in individuals beyond the age of 35, is indeed a familiar though often disconcerting situation. Bauer¹ has often emphasized his contention that the galactose tolerance test provides an exact differentiation between these two types of jaundice, for his results were consistently negative in the obstructive form and distinctly positive in the intrahepatic form, unless the latter was of a very mild nature. The observations of other German investigators tended in the main to corroborate these findings. Davies,² although agreeing with these results, felt that no interpretation should be based on this single test of liver function.

In this country, little clinical recognition was accorded these contributions until the papers of Shay and Schloss^{3,4,5} appeared, corroborating Bauer's earlier conclusions. They explained these differences in galactose tolerance on a pathologic basis. In the toxic or intrahepatic form an acute or subacute, diffuse, hepatic, parenchymal damage occurs with a resultant derangement in the carbohydrate function, in the obstructive form, in which hepatic destruction is progressing slowly, the regenerative and reserve powers of the liver permit of a normal carbohydrate function. Recently, in a study of 68 confirmed cases of obstructive jaundice, Banks, Sprague and Snell⁶ found positive results in one-third of the benign group and in approximately 46 per cent of the malignant group, while of 18 cases of acute or subacute intrahepatic jaundice, 84 per cent were positive. They felt that the galactose test might be of value in doubtful cases. Latterly, Tumen and Piersol²⁴ found the test "practically always negative" in obstructive jaundice and positive in the majority of cases of toxic hepatitis and catarrhal jaundice. They regarded it as of definite diagnostic value.

The use of the urobilinogen test in clinical jaundice is based upon the generally accepted view⁷⁻⁸ that urobilinogen is formed from bilirubin by the action of certain putrefactive bacteria of the intestine and is eliminated in part through the kidneys. The disappearance or absence of urobilinogen from the urine in obstructive jaundice has frequently been noted^{1,9,11-16,17-19} since the early observation of Muller,⁷ yet one is able to cull from the literature only a few references directing attention to its potential diagnostic value. Bauer^{16,20} and Wallace and Diamond^{16,17,18} found excessive

* Presented before the Section on Gastroenterology and Proctology at the Cleveland Session of the American Medical Association, June 14, 1934.

From the Departments of Medicine and Physiology, Northwestern University Medical School and from the Medical Service of the Cook County Hospital.

amounts of urobilinogen in the urine during the beginning and end of catarrhal jaundice, and only traces or a total absence during the height of the jaundice, when very little if any bile is being excreted into the intestine. From their studies, Wallace and Diamond,^{16, 17, 18} and later Davies,² concluded that the presence of urobilinogen in the urine points to an intrahepatic jaundice, whereas its constant absence bespeaks an obstructive jaundice.

In the present investigation, an attempt has been made to evaluate the respective merits of these tests, also to ascertain any relative superiority and to determine the virtue of supplementing one test by the other.

MATERIAL AND METHODS

This report deals with the results of studies conducted on a total of 30 patients. Of this series, 16 were cases of obstructive jaundice, which in four was due to a stone and in 12 to a malignant process. The diagnosis in 15 of these cases was confirmed either by necropsy or by operation, and in the other one the clinical diagnosis was definite. Of the remaining 14, there were 12 patients with acute or subacute intrahepatic jaundice, in one of these, the diagnosis was based upon necropsy studies, and in 11 upon the clinical history, the signs and the course which led to ultimate complete recovery. Of the remaining two patients with chronic intrahepatic jaundice (cirrhosis), the diagnosis in one was confirmed at necropsy. Except for these two cases of cirrhosis, only those patients in whom the differential diagnosis between obstructive and intrahepatic jaundice was of primary importance, were selected. The course of the jaundice was followed by repeated determinations of the icterus index. In all cases, studies were instituted as soon as it was feasible, in order to facilitate an early diagnosis.

The technic of the galactose test was identical with that described by Shay, Schloss and Rodis^{3, 4, 5} and was based upon the original work of Bauer. After an overnight fast, the patient voids and the specimen is saved as a control. He is then given exactly 40 gm of pure galactose, dissolved in 500 c c of water and flavored with a few drops of lemon juice. Urine specimens are collected hourly for five hours and placed in separate containers. During the period of the test the patient may drink water if he desires, but nothing else. Each specimen is tested for sugar by the Benedict qualitative method. Those specimens which are positive are mixed and the total amount of sugar is determined by the Benedict quantitative method. An excretion of more than 3 gm of galactose was considered indicative of an intrahepatic jaundice. No diabetics were encountered in this series.

The Ehrlich's aldehyde reaction was chosen for the detection of urobilinogen. The technic consisted of adding 1 c c of Ehrlich's reagent (2 gm paradimethylamidobenzaldehyde in 100 c c of 20 per cent HCl) to 10 to 15 c c of urine. If positive, a red color appeared within 3 to 5

minutes The Wallace and Diamond method of quantitation was used in the early part of this work, but it was soon found that the quantity could be expressed satisfactorily in terms of 1 plus to 4 plus, depending on the depth and rapidity of color formation Normally, urobilinogen excretion, although varying from hour to hour, is greatest when the metabolic processes are at their height, usually in the afternoon Accordingly, urine was obtained before or shortly after lunch and the test was applied immediately In those cases in which urobilinogen was absent, daily examinations were made and at least two late afternoon specimens were examined During the period of observation, no patient received antipyrine or hexamethylamine and the absence of acetone from the urine was ascertained, thereby eliminating pseudo-positive reactions

RESULTS

Acute and Subacute Intrahepatic Jaundice In table 1 are recorded the results of observations on 10 patients with "catarrhal jaundice," one with cinchophen poisoning and one with alcoholic steatosis In the majority, the age was beyond 35, a circumstance which is of special interest to us because of its relationship to the so-called "cancer age" The duration of the icterus from the time of its inception to the day of the galactose test varied from five days to six weeks with a mean average of 17 days In two patients of this group (cases 6 and 10), the jaundice was already subsiding at the time that the galactose test was applied, thereby accounting for the normal response Of the remaining 10 patients, seven excreted galactose in amounts greater than the adopted maximum of normal, in the other three, the excretion was well within normal It is noteworthy that the jaundice in these latter three cases (cases 2, 9 and 12) was at its maximum at the time of the test and that it was particularly intense in case 9 The greatest excretion encountered (6.4 gm) was observed in case 5, at a time when the jaundice had begun to subside (Unfortunately this patient was not seen when the icterus index was at its peak) From these results there appears to be no relationship between the degree of icterus in different persons and the amount of galactose excreted

Case 12 is worthy of special comment, for it exemplifies the point made by Shay, Schloss and Rodis namely, that an extensive and very diffuse process is essential for the production of an abnormal galactose output Even though the galactose test was normal, the liver sections showed a marked alteration of the parenchyma with most of the liver cells filled with large fat droplets and the remaining ones distinctly swollen

In all of the 12 cases, urobilinogen was detected in the urine at one time or another In three instances it was consistently absent during the early period of observation but in none was it absent longer than seven days It always appeared later in gradually increasing amounts It must be emphasized that it is of the greatest importance to examine fresh specimens

TABLE I
Acute and Subacute Intrahepatic Jaundice

| Case | Age | Sex | Duration of Jaundice | Icterus Index | Galactose Excretion (Gm) 4 45 | Urobilinogen* | Diagnosis** | Comment |
|------|-----|-----|----------------------|----------------|-------------------------------|---------------------|------------------------------------|---|
| 1 | 28 | M | 6 weeks | 150 | | Trace | "Catarrhal Jaundice" | Urobilinogen + + + + one week after galactose test |
| 2 | 48 | M | 15 days | 93 | 1 80 | 0+ to + + + + | "Catarrhal Jaundice" | Urobilinogen absent for 1 week. No oliguria, vomiting, diarrhea or dehydration |
| 3 | 27 | M | 2 weeks | 77 | 4 00 | Trace | "Catarrhal Jaundice" | - - - - |
| 4 | 27 | M | 9 days | 118 | 4 90 | 0+ to + + + + | "Catarrhal Jaundice" | Urobilinogen absent for 4 days |
| 5 | 41 | M | 15 days | 45 (Subsiding) | 6 40 | +, later + + + + | "Catarrhal Jaundice" | Icterus index 90, 10 days before galactose test Common duct stone strongly considered |
| 6 | 38 | M | 2 weeks | 37 (Subsiding) | 0 00 | Trace to + | "Catarrhal Jaundice" | Icterus index 64, one week before galactose test |

P M Postmortem

immediately and repeatedly. In cases 2 and 9, which yielded a normal galactose response, such repeated urobilinogen studies proved in retrospect to be of inestimable value, for although these cases simulated catarrhal jaundice clinically, a suggestive history of biliary colic in the face of a negative galactose test (pointing to an obstructive jaundice) proved misleading, and only the urobilinogen excretion curve together with the subsequent clinical course revealed the true nature of the illness. Another case in point attesting its value and indicating the need of a more universal application of the urobilinogen test, is that of patient 10, a man of 55 who presented himself with the symptoms of a painless, progressive jaundice of four weeks' duration, accompanied by a loss of 20 pounds, and concerning whom no definite decision between catarrhal jaundice and carcinoma of the head of the pancreas could be reached. An exploratory laparotomy was deemed advisable, but, because of a consistently positive urobilinogen test, operation was postponed. The subsequent course, characterized by a decline in the jaundice with complete recovery, justified such conservative management.*

Chronic Intrahepatic Jaundice A proved case of cholangiolitic cirrhosis and a clinical case of biliary cirrhosis are included in this category (table 2). The jaundice was intermittent in each instance, and in one had been noted as long as three years before admission. In both, the galactose tolerance test was normal irrespective of the degree of jaundice, and the urobilinogen test was strongly positive.

Obstructive Jaundice This group is represented by 16 cases, in four of which the common duct was occluded by a stone and in 12 by an extrahepatic malignancy (table 3). It is particularly in the latter type of obstruction, so frequently painless in onset, that keen interest attaches to the correct diagnosis and especially prognosis. The age incidence in the cases of malignancy varied from 36 to 77, and the jaundice was of two weeks' to five months' duration, the average being approximately two months. In all 16 cases of obstructive jaundice the galactose excretion was normal. This includes a case of intermittent hepatic fever with jaundice of seven and a half months' duration.

In 10 of the 12 cases of malignancy, urobilinogen was not detected during the entire period of observation, in one, although present in traces during the first five days, it subsequently disappeared and remained consistently absent, in another (case 20), traces were always found, but in this instance the obstruction had not yet become complete. In the cases of obstruction by a stone, urobilinogen was present in varying amounts at one time or another. It is apparent from case 20 that difficulty may be encountered in differentiating an obstructing stone from incomplete occlusion by a new growth, in which instance we must rely upon a carefully

* Because of certain technical difficulties in this case, the galactose test could not be performed when the jaundice was at its maximum. Later, the response was normal but by this time the icterus index was much lower.

TABLE II
Chronic Intrahepatic Jaundice

| Case | Age | Sex | Duration of Jaundice | Icterus Index | Galactose Excretion | Urobilinogen | Diagnosis | Comment |
|------|-----|-----|----------------------|---------------|---------------------|--------------|--|--|
| 13 | 43 | M | 6 months | 18 | (Gm) 2.50 | ++++ | Cholangiolitic cirrhosis with chronic splenic tumor (P.M.) | Jaundice for 6 months before galactose test Intermittent and remittent jaundice for 3 years |
| 14 | 32 | M | 9 weeks | 53 | 0.65 | ++++ | Biliary cirrhosis (Clinical) | Recurrent ascites Intermittent jaundice Liver greatly enlarged Moderate splenomegaly |

taken history along with the usual clinical and laboratory studies, and, as emphasized by Piersol, Bockus and Shay^{25, 26} and others, upon the presence or absence of cholesterol and bilirubin-calcium crystals in the bile, or, failing in these, prolonged observation of the urobilinogen excretion (case 21) may give us information of a decisive nature.

The persistence of traces of urobilinogen or its subsequent reappearance in experimentally produced complete biliary obstruction has been noted by Wilbur and Addis⁹ and by others^{11, 16, 17, 18, 21}. While these findings did not obtain in our clinical series, such possibilities deserve recognition. From the recent experimental work of Salmon²¹ they appear to be dependent upon the blood bilirubin concentration and the duration of the obstruction. Significant in this respect too, is the presence of bilirubin in the intestinal mucosa of such animals, noted by Gerhardt²² and by others^{11, 23} and presumably indicating a slight leakage of bile pigment through the intestinal wall into the lumen, probably through the casting off of epithelial cells.

COMMENT

From the present study of 30 selected cases of jaundice it is apparent that the galactose test, supplemented by the urobilinogen test, may furnish us with diagnostic data very often of an unequivocal nature. Indeed, Bauer¹⁶ has found these two tests of distinct value, and Davies has referred to the advantage of combining the galactose test with other tests of liver function, including the urobilin test.

In all of our cases of obstructive jaundice, either benign or malignant, irrespective of the duration of the jaundice, the galactose test was negative. In those with complete obstruction, the Ehrlich's aldehyde reagent failed to reveal the presence of urobilinogen in the urine, when the obstruction was incomplete but of a constantly increasing degree, urobilinogen was always detected, though never present in more than traces. In acute or subacute intrahepatic jaundice, if we exclude those cases in which negative results were obtained when the icterus was already subsiding, the galactose test was found positive in seven of the remaining 10. In all cases with this type of jaundice, urobilinogen was present in the urine in variable amounts at one time or another, ultimately appearing in large quantities if the period of observation was sufficiently prolonged.

It is in those cases which do not conform to the rule of the majority that the combined use of the urobilinogen and the galactose tests appears to be of reciprocal value and finds its greatest field of usefulness. Cases 2 and 9 are representative of what was interpreted to be obstructive jaundice, principally on the basis of the normal galactose response, but in which the final picture was elucidated by the repeated, supplementary, urobilinogen studies. Contrariwise, in case 20, an instance of incomplete obstructive jaundice with constant traces of urobilinogen in the urine, it was the nega-

tive galactose test which disclosed the true nature of the morbid process. From this point of view, the report of Banks, Sprague and Snell is of practical interest to us, for although the high percentage of positive results with the galactose test in the obstructive group is at variance with the findings of Bauer, Davies, Shay, Schloss and Rodis, Tumen and Pierson and also with those of the present study, it would seem that the urobilinogen test might be of considerable value in such cases. Finally, we must recall the possibility that a secondary ascending infection of the biliary tract by certain reducing bacteria,^{15, 16, 17, 18} occurring in a case of complete occlusion, may be accompanied by the appearance of urobilinogen in the urine and hence lead us to suspect an intrahepatic jaundice. In such cases the galactose test if negative may be of significant utility.

We may conclude from this study that the urobilinogen and the galactose tests taken individually are truly worthy of clinical acceptance and application. It is more difficult to make final deductions concerning their relative superiority. Yet from an analysis of these cases, the urobilinogen test appears to be more reliable than the galactose test in differentiating intrahepatic from obstructive jaundice. Again, the several factors of error, such as oliguria, dehydration, vomiting and gastric stasis, which may preclude the use of the galactose test or militate against a correct interpretation of its excretion,⁹ do not seem to play a significant rôle in the outcome of the urobilinogen test. The combined use of these tests, however, may provide us with more decisive information and contribute to a more intimate understanding of the nature of the underlying disease.

SUMMARY

1 Galactose and urobilinogen determinations were made on 12 cases of acute and subacute intrahepatic jaundice, two cases of chronic intrahepatic jaundice and 16 cases of obstructive jaundice.

2 Seven cases of acute and subacute intrahepatic jaundice yielded abnormal galactose responses. Of the remaining five with a normal response, in two the jaundice was already subsiding when the galactose test was performed. Urobilinogen was detected in the urine of all cases of this group at one time or another.

3 The galactose test was normal and the urobilinogen test was strongly positive in both cases of chronic intrahepatic jaundice.

4 In the obstructive group the galactose test was uniformly negative. Urobilinogen was absent from the urine of all cases of complete obstruction.

5 Individually, these tests are worthy of clinical acceptance, although from this study the urobilinogen test seems the more reliable.

6 Utilization of both the galactose and the urobilinogen (urinary) tests is advocated in the routine clinical study of jaundice.

Note The author wishes to express his indebtedness to Dr A. C. Ivy for his generous cooperation, also to Dr William Bruns for his kind suggestions and to Dr R. H. Jaffe for the privilege of studying the necropsy material.

THE PLEURAL AND PULMONARY COMPLICATIONS OF CARCINOMA OF THE ESOPHAGUS^{*}

By CHESTER S. KLEFER, M.D., F.A.C.P., *Boston, Massachusetts*

INTRODUCTION

ONE of the ways carcinoma of the esophagus may disguise itself is in the form of a chronic pleural or pulmonary infection. This usually is the result of a perforation of the esophagus into the trachea, bronchi, mediastinum, lung or pleura. In some cases, food or fluid is aspirated into the air passages due to the obstruction of the esophagus, or a necrotic lymph node which is the site of metastases may perforate into both the lung and esophagus producing a fistula. In other cases, the trachea or bronchi may be obstructed due to the invasion of the tumor growth or as a result of pressure from enlarged lymph nodes which are the site of metastases. In these, the complications of tracheo-bronchial stenosis arise. At this time, the observations of 17 cases of carcinoma of the esophagus in which there were pleural or pulmonary complications are recorded.

Before proceeding with the details of the cases, it is necessary to point out that the site and frequency of pleuro-pulmonary complications in carcinoma of the esophagus will naturally depend upon the exact type of tumor and its location. It is well known that squamous cell carcinoma of the esophagus ulcerates frequently, and in these cases perforation is seen commonly. Adenocarcinoma of the esophagus, on the other hand, ulcerates less often and produces obstructive symptoms earlier.

The upper third of the esophagus is in close contact with the trachea, the carotid arteries and the recurrent laryngeal nerve. In the medial third, it is in close contact with the trachea, left bronchus, the intercostal arteries, the thoracic duct, the hemiazygos veins, aortic arch, left subclavian artery and left pleura. In the lower third, it is in close contact with the left auricle of the heart, the pericardium and descending thoracic aorta.

It is of some significance that tumors of the esophagus commonly metastasize to the mediastinal lymph nodes. These enlarged nodes may invade the lung or trachea, compress the esophagus at some distance from the primary growth or cause unilateral or bilateral paralysis of the recurrent laryngeal nerves. In a few cases, the cancer may invade the veins so that venous thrombosis or widespread metastases in the lungs or elsewhere are observed.

A summary of the cases is presented in table 1.

TABLE I
Summary of 17 Cases of Carcinoma of the Esophagus with Pleural and Pulmonary Complications

| Case No | Location of Carcinoma | Site of Perforation | Physical Signs | Anatomical Lesions | Fever | W B C | Duration of Illness | Symptoms | Remarks |
|--------------|-----------------------|-------------------------|---|--|-------------|---------------|---------------------|---|---|
| 1 ♂ 70 | Middle third | Left bronchus | Pleural effusion Left thoracic cavity | Bronchopneumonia left lower lobe | 98.6-101.5° | 16 800 | 7 months | Epigastric pain Dysphagia Coughing following ingestion of food Hematemesis | Hematemesis caused death |
| 2 ♂ 62 | Middle third | Trachea | Bilateral bronchopneumonia | Bilateral bronchopneumonia | 98.6-100.0° | 19 800-20 720 | 5 months | Epigastric pain Dysphagia Regurgitation of food Coughing following ingestion of food or water Purulent sputum | Recurrent laryngeal paralysis |
| 3 ♂ 50 | Middle third | Trachea | Mediastinal widening Rales over both lower lobes | Bilateral suppurative bronchopneumonia | 99-101° | 12 000 | 5 months | Dysphagia Coughing following swallowing Pain in mid sternum | |
| 4 ♂ 72 | Middle third | Left bronchus | Pleural effusion Left pleural cavity Bronchopneumonia left lower lobe | Diffuse bronchopneumonia left lower lobe Pleural effusion | 99-102.5° | 16 800-32 000 | 7 months | Pain in epigastrum Dysphagia Coughing following swallowing | Cirrhosis of liver Metastases to glands at hilum of left lung Hematemesis caused death |
| 5 ♂ 53 | Middle third | Trachea | Superior mediastinal mass | Bilateral bronchopneumonia | 101-102° | 9 000 | 9 months | Hoarseness Dysphagia Coughing following swallowing | Recurrent laryngeal paralysis, right side Mass in superior mediastinum Enlarged glands above right clavicle Perforation observed in trachea with bronchoscope |
| 6 ♂ 59 | Lower third | Left lower lobe of lung | Lung abscess left lower lobe Solidification of left lower lobe | Lung abscess left lower lobe | 99-103° | 18 000-22 000 | 9 months | Dysphagia Pain in chest Cough Copious amounts of sputum | Clubbed fingers Elastic tissue in sputum |
| 7 ♂ 70 | Middle third | None | Signs of solidification of left upper lobe | Lung abscess left upper lobe Narrowing of trachea and left superior bronchus | 99-102° | 12 000 | 8 months | Pain beneath manubrium Coughing after swallowing | Fatal hematemesis Ulceration of vessels |
| 8 ♂ 68 | Upper third | None | Signs of solidification and cavity formation in left upper lobe | Lung abscess left upper lobe Direct extension of infection from cancer to lung | 99-101° | 10 000 | 7 months | Loss of weight Substernal pain Cough and expectoration No dysphagia | Metastases to lung—pleura—peritoneum |

TABLE I (Continued)

| Case No. | Location of Carcinoma | Site of Perforation | Physical Signs | Anatomical Lesions | Fever | W B C | Duration of illness | Symptoms | Remarks |
|---------------|-----------------------|-----------------------------------|--|--|-----------|--------------|---------------------|--|---|
| 9 ♂ 50 | Lower third | Right lung and pleura | Signs of solidification and fluid—right lower lobe | Pneumonia with abscess formation, right lower lobe. Empyema, right pleural cavity. | 99–102.5° | 14 000 | 7 months | Dysphagia. Cough. Epigastric pain. Coughing following swallowing. Pain in right chest. | |
| 10 ♂ 52 | Lower third | Right lung | Rales and dullness over right lower lobe. | Abscess cavity in upper part of right lower lobe. | 100–102° | 13 000 | 2 months | No dysphagia. Cough with copious amounts of sputum. | |
| 11 ♂ 63 | Upper third | None | Solidification of right upper lobe. | Pneumonia and gangrene of right upper lobe. Acute fibrinous pleuritis. | 98–101° | 12 000 | 6 months | Dysphagia—6 months. | Colitis and peritonitis. |
| 12 ♂ 46 | Lower third | Right pleural cavity | Pleural effusion, right side. | Empyema, right pleural cavity. | 99–101° | 26 310 | 2 months | Pain in right chest. | Tuberculosis of pleura. |
| 13 ♂ 52 | Middle third | None | Cervical glandular enlargement. | Multiple metastases in lungs. | 98 | 11 000 | 4 months | Cough and expectoration. Dyspnea. Swelling of neck. | Metastases to cervical and axillary lymph nodes, lungs. |
| 14 ♂ 51 | Middle third | None | Tracheal stenosis. Bilateral bronchopneumonia. | Bilateral bronchopneumonia. | 102–104° | 8 350 | 5 months | Dysphagia. | Recurrent laryngeal paralysis. |
| 15 ♂ 42 | Middle third | Mediastinum | No pulmonary signs. | Carcinoma of esophagus. Ulceration and perforation. Mediastinal abscess. Acute pericarditis. | None | 10 000 | 6 months | Acute symptoms of mediastinitis one day. Dyspnea. Liquid cyanosis of upper half of body. | |
| 16 ♂ 58 | Lower third | Upper third. Necrotic lymph node. | Dyspnea. Tracheal obstruction. Fixation of trachea. Mediastinal tumor. | Carcinoma of esophagus with ulceration in lower third. Necrotic lymph nodes perforating esophagus and communicating with the right upper lobe. | 99–103° | 11 400 | 4 months | Weakness—14 weeks. Hoarseness—12 weeks. Loss of weight. Pain and cough. | Obstruction to esophagus in upper third due to lymph nodes—no obstruction at site of tumor. |
| 17 ♂ 60 | Middle third | Bifurcation of trachea. | | Tracheo-esophageal fistula. Pneumonia—R L L R M L. | 101–103° | 9 000–13 700 | 7 months | Dysphagia—2 months. Anorexia—7 months. Cough and expectoration—1 month. | |

The lesions responsible for the pulmonary and pleural signs are summarized in table 2, and the anatomical findings are listed in table 3

COMMENT—GENERAL FEATURES

All of the patients were men between the ages of 50 and 72 years. The primary lesion was located in the middle third of the esophagus in ten, in the lower third in five and in the upper third in two. The duration of the disease varied from two to nine months after the onset of the first symptom indicating disease. Once pulmonary or pleural signs became manifest there was fever varying from 98.6° to 103° F or higher, and a leukocytosis between 9,000 and 32,000 per cubic millimeter. The symptoms and signs varied in accordance with the type of anatomical lesion and are discussed separately.

Perforation of Carcinoma of the Esophagus into the Trachea or Bronchi
In the group of cases reported here the trachea was perforated in four cases and the left bronchus in two. In all of them, the carcinoma arose in the

middle third of the esophagus. The symptoms and signs that developed following this complication were highly characteristic and consisted of *paroxysms of coughing and suffocation following the ingestion of fluid or food*. They were due to the passage of foreign material into the trachea or bronchi from the esophagus. After these symptoms and signs had been present for a varying period of time, evidences of pulmonary infection appeared, such as pneumonia or abscess formation. When the fistula was between the trachea and the esophagus the signs were either unilateral or bilateral, when there was a broncho-esophageal fistula the signs were unilateral, the side affected depending upon the bronchus perforated.

The details of an illustrative case of tracheo esophageal fistula are recorded in case 1.

CASE I

A man, 60 years of age, was admitted to the hospital, complaining of difficulty in swallowing. Seven months before admission anorexia had begun, and two months before entry he noticed dysphagia and the regurgitation of solid food. This had increased until he could swallow only liquids. The examination at this time revealed evidence of loss of weight and a narrowing of the lumen of the esophagus at about the bifurcation of the trachea. Following a liquid diet and tincture of belladonna the patient's symptoms were relieved somewhat for about two months. Then the symptoms of dysphagia became worse and attacks of coughing developed following the ingestion of liquids. There was dull pain beneath the sternum which was increased by coughing. The cough was soon accompanied by the expectoration of dark-colored, foul-smelling sputum which was blood-tinged. For one week he had been hoarse. Examination at this time showed fever, emaciation, pallor, moderately enlarged lymph nodes in the supraclavicular fossae, fetor oris, impaired resonance and many fine rales over the right middle and right lower lobe, with bronchial breathing. Roentgen-ray examination showed infiltration of the lower half of the right lung. The white blood cell count was 10,000 per cubic millimeter. The sputum was foul-smelling and abundant, and there was moderate anemia. The clinical course was one of progressive failure, with high irregular fever, loss of weight and the signs of a diffuse suppurative pulmonary disease.

Necropsy showed a squamous cell carcinoma of the middle third of the esophagus which had perforated the trachea at the bifurcation, and pneumonia with abscess formation of the right middle and lower lobes.

Briefly, then, this case illustrates the sequence of events when a carcinoma perforates into the trachea at its bifurcation.

Inasmuch as carcinomata of the esophagus are most common in its upper and median third, it is not surprising that the trachea or bronchi are often invaded or perforated by the tumor. From general experience,^{1, 2, 3} it is commoner to observe perforation of the trachea than of the bronchi, and when the latter are involved either one may be perforated. The left usually is perforated directly by the tumor mass, whereas the right is more often invaded by an abscess from the mediastinum which has resulted from perforation of the esophagus. In the cases collected by Zenker and Ziemssen³ the right bronchus was involved more often than the left.

Perforation of the Carcinoma of the Esophagus into the Lungs or Pleural Cavities The lungs or pleurae were the site of infection in five cases due to perforation of the esophagus and the direct extension of the infection into these structures. In four, the carcinoma arose in the lower third of the esophagus and the perforation caused right-sided empyema in one, abscess of the right lower lobe in two with empyema in one, and an abscess in the left lower lobe in another. In the remaining case, the upper third of the esophagus was perforated and the left upper lung lobe invaded. Aside from these cases in which perforation of the carcinoma was responsible for the pulmonary complication, a sterile pleural effusion was observed in two patients with a broncho-esophageal fistula and a bronchopneumonia.

From these cases, and others reported in the literature, the right lung or pleura is more often involved than the left when a carcinoma of the lower third of the esophagus perforates. The same is true when a pneumothorax occurs as a complication. The following case illustrates the course of events when the lung is invaded by a perforating carcinoma.

CASE VI

A man, aged 59 years, complained of "cough and stomach trouble." Nine months before admission he began to notice anorexia and a burning sensation in the lower part of the left side of his chest which came on soon after eating. Six months after the onset of symptoms he developed pain in the left side of the chest on respiration. The cough increased and was productive of large amounts of foul-smelling mucopurulent sputum. At the same time he noticed increasing difficulty in swallowing so that only liquids could be taken with ease and comfort. Upon examination, it was found that he had lost weight and coughed frequently. There was distinct clubbing of the fingers and pallor. Over the left lower lobe posteriorly there were dullness and rales. Roentgen-ray examination revealed slight cloudiness of the left lower lobe. The red blood cell count was 4,000,000 per cubic centimeter, the hemoglobin 65 per cent and the white blood cell count 22,000 per cubic millimeter. The sputum contained elastic tissue. High, irregular fever developed and the signs at the left lower lobe became more extensive with areas of solidification which were confirmed by further roentgen-ray examinations. The presence of a fistula between the esophagus and lung was established clinically by having the patient swallow capsules containing carmine, and then observing carmine in the sputum as long as three days later. The lesions progressed and the patient died. Necropsy showed a carcinoma of the lower third of the esophagus invading the left lung with abscess formation in the left lower lobe and metastases to the subdiaphragmatic lymph nodes.

This case illustrates, then, the results of a perforation of the lower third of the esophagus with an invasion of the left lower lobe, bronchopneumonia and multiple abscesses.

Tracheal or bronchial obstruction may arise as the result of a direct invasion of an esophageal tumor, or of a lymph node involved by a metastasis compressing either the trachea or bronchi. Three examples of these complications were observed. In all, the signs of tracheal or bronchial stenosis were present. In the case of tracheal obstruction, bilateral bronchopneumonia developed as a complication. In the patient with bronchial

obstruction, an abscess of the lung appeared. The following case is illustrative of tracheal stenosis resulting from an enlarged lymph node, containing tumor, in a patient with a carcinoma in the lower third of the esophagus.

CASE XIV

A white man, 51 years of age, entered the hospital complaining that for the past four months food had repeatedly caught in his throat. The difficulty in swallowing had increased progressively but there had been no regurgitation of food. Upon examination, it was found that he had lost weight and was hoarse. There was paralysis of the left abductor muscle of the larynx, attributed to compression of the recurrent laryngeal nerve. Attacks of coughing coming on after the ingestion of large amounts of fluid may also have played a part in causing hoarseness. The trachea was fixed in the midline; the lungs were normal to physical and roentgen-ray examination. He had a moderate anemia, 3,770,000 red blood cells and 65 per cent hemoglobin, and a normal white blood cell count. Roentgen-ray examination showed a constriction of the esophagus in its middle third which was compatible with the diagnosis of carcinoma. He was treated by dilating the esophagus with bougies and obtained temporary relief from his dysphagia for approximately four months, when he began to have severe attacks of coughing and difficulty in breathing. These attacks followed the swallowing of liquids, and he frequently coughed up small particles of food.

At this time the examination showed an ill man who appeared prostrated and worn. There was obvious dyspnea with wheezing respiration suggesting tracheal obstruction. There was fever, cough, expectoration and hoarseness. There were no enlarged lymph nodes above the clavicle but there was fixation of the trachea to lateral movement, and it seemed to be displaced anteriorly. The lungs showed the signs of a bilateral bronchopneumonia. Otherwise the examination showed nothing remarkable. He failed rapidly and died nine months after the onset of symptoms. Necropsy showed a carcinoma of the middle third of the esophagus which had ulcerated but not perforated. There were large metastatic lymph nodes in the superior mediastinum which had produced recurrent laryngeal paralysis, tracheal and esophageal stenosis. There was a bilateral aspiration pneumonia.

In this case, then, there were two obstructive lesions of the esophagus, one at the site of the carcinoma, the other at the site of the enlarged lymph nodes in the superior mediastinum. The latter had produced, in addition, a stenosis of the trachea which was responsible for the physical signs and the bilateral bronchopneumonia.

In other cases, enlarged lymph nodes in the superior mediastinum, from carcinoma of the lower part of the esophagus, not only compress the esophagus as in case 14, but in addition they may cause perforations in such a manner that there is a communication between the esophagus and the lung. For instance, the following case.

CASE XVI

A man, 58 years of age, complained of weakness and hoarseness of 14 weeks' duration. Accompanying these symptoms there was pain beneath the sternum, an unproductive cough, expectoration of small amounts of sputum, anorexia, progressive weakness and loss of weight. On examination there was hoarseness, stridor, cyanosis of the head with fullness of the neck. The larynx was prominent and fixed so that

it could not be moved laterally. The lungs showed signs of emphysema. There was paralysis of the right abductor muscle of the larynx, moderate increase in the retro-manubrial dullness. The roentgen-ray examination showed a mass in the superior mediastinum. Fluoroscopic examination of the esophagus showed some delay in the passage of barium through the upper third of the esophagus.

Following roentgen-ray treatment over the mediastinum there was an increase in the cough with difficulty in swallowing, and the appearance of solidification and abscess formation in the right upper lobe, high irregular fever and leukocytosis.

Necropsy showed a non-obstructive carcinoma of the lower third of the esophagus. There were metastases in the lymph nodes of the mediastinum and these had invaded the esophagus, the trachea and the lung, and had produced a fistula between the eroded esophagus and the upper lobe of the right lung.

This case illustrates that lymph nodes with metastases not only produce obstruction but that they may cause perforation of the esophagus and fistulous communications.

When the obstruction to the esophagus is in the upper third, the ingestion of food or fluid may be followed by an overflow from the esophagus into the trachea. This produces paroxysms of coughing, and may lead to aspiration lung abscesses, as in case 11.

In summary, then, pulmonary or pleural infections arise during the course of carcinoma of the esophagus by perforation of the growth into the lung, trachea, bronchi or pleura. An enlarged lymph node, due to metastatic tumor, may cause tracheal compression, or it may perforate both the esophagus and lung, producing a fistula. Finally, food may be aspirated into the trachea when there is obstruction.

Carcinoma of the Esophagus with Multiple Pulmonary Metastases

Rarely a carcinoma of the esophagus may remain latent and the manifestations become those of multiple tumor metastases in the lungs, as in the following case.

CASE XIV

A white man, 52 years of age, complained of irritation in his throat, which produced coughing without expectoration, of two months' duration. For six weeks he had had dyspnea on exertion, and a painless swelling on the left side of the neck in the supraclavicular region. Upon examination, it was found that he had lost a considerable amount of weight, and that there were masses of lymph nodes above the clavicles on both sides. The thyroid gland was irregular and nodular, there was increased retromanubrial dullness, but the heart and lungs were negative to physical examination. Roentgen-ray examination of the chest showed numerous round, dense areas characteristic of metastases to the lung. Roentgen-ray studies of the esophagus did not reveal any obstruction. Biopsy of a lymph node from the supraclavicular region revealed a metastatic carcinoma. The patient failed rapidly, and at necropsy a small non-obstructing carcinoma of the lower third of the esophagus with multiple metastases to the lungs and lymph nodes was found.

Differential Diagnosis Two conditions which may be confused with carcinoma of the esophagus and its pulmonary complications are aneurysm of the aorta compressing and eroding the esophagus, and carcinoma of the

lung producing esophageal symptoms. The following two cases are examples.

CASE XVIII

A man, 56 years of age, complained of difficulty in swallowing. Two months before admission he began to notice pain in the right side of the chest and dyspnea. These symptoms increased until one month before entry when he noticed dysphagia for solid food, this increased until it was impossible for him to swallow even liquids. He was well developed but had lost considerable weight. The examination of the chest revealed some dullness at the right base and the signs of a high right diaphragm. There were no signs of an aneurysm of the ascending, transverse or descending part of the arch of the aorta. The heart sounds were clear. Roentgen-ray examination of the chest showed a high right diaphragm with fibrosis of the right lower lobe of the lung. Due to the esophageal obstruction, a gastrostomy was done. Three days later there were signs of consolidation over the lower lobe of the right lung. A day later a to-and-fro friction rub appeared over the heart, and he died the same day.

Necropsy showed an aneurysm of the descending aorta which had ruptured into the mediastinum, forming a hematoma which had caused esophageal obstruction, necrosis and perforation of the esophageal wall and an abscess of both the mediastinum and right lung, and an acute pericarditis.

In this case the pulmonary signs resulted from a perforation of the esophagus due to erosion from a hematoma which arose from a ruptured aneurysm. The signs were predominantly esophageal and pulmonary.

In the following case, the carcinoma arose in the lung and invaded the esophagus causing necrosis and perforation.

CASE XIX

A white man, 80 years of age, complained of difficulty in swallowing. Four months before entry he began to have a severe distressing cough which was non-productive in character. Three weeks before admission he developed dysphagia and was unable to swallow any solid foods, and for one week he had regurgitated both food and water. He had had pain in the left axillary region and back which was exaggerated by respiratory effort. There was progressive hoarseness and loss of weight. On examination he was found to be thin, emaciated and dehydrated. The trachea was deviated to the left and the left side of the chest moved only slightly during respiration. Over the left lower lung lobe there were physical signs of fluid and above this area signs of solidification and of a fibrous pleurisy. The right lung was clear. The heart was displaced to the right but the sounds were clear. There was evidence of a paralysis of the inferior cervical sympathetic ganglion with a Horner's syndrome. There was a moderate anemia and a white blood cell count of 12,000. The pleural fluid was cloudy and contained many leukocytes and pneumococci type V. A gastrostomy was done on account of the dysphagia, and death followed one week later.

Necropsy showed a carcinoma of the left lung invading the mediastinum and esophagus with erosion of the latter, abscess formation in the lung and empyema of the left pleural cavity.

In this patient the esophagus was invaded and perforated by a tumor arising in the lung with resultant infection of both the left lung and pleura.

From the description of these cases, it is manifest that during the course

of a carcinoma of the esophagus a variety of pleural and pulmonary complications may arise which may imitate a large number of primary pleural or pulmonary disorders. In addition, there are a few extrinsic lesions of the esophagus that may produce not only esophageal but pulmonary symptoms and signs as well.

SUMMARY

1 Seventeen cases of carcinoma of the esophagus are recorded in which pleural or pulmonary complications were the outstanding features of the disease.

2 Pleural and pulmonary complications of carcinoma of the esophagus result from perforation of the growth into the trachea, bronchi, lungs or pleurae, or as the result of obstruction of the air passages, of the aspiration of food, or of perforation of the lung by a necrotic metastasis in a lymph node.

3 The symptoms and signs caused by these complications may completely dominate the clinical picture and overshadow symptoms of the primary lesion.

4 The conditions that are to be discriminated from these complications are discussed.

FURTHER OBSERVATIONS ON THE HEART IN MYXEDEMA¹

By J LERMAN, M D, R J CLARK, M D, and J H MEANS, M D,
F A C P, *Boston, Massachusetts*

IN a previous paper¹ we presented data dealing with changes in the size of the heart, in the blood pressure and in the electrocardiograms resulting from thyroid medication in myxedema patients. The most striking finding was a shrinkage in the transverse diameter of the heart of from 1 to 7 cm in 20 of the 30 patients observed. Since then 18 additional patients have been studied. Forty-seven teleroentgenograms were obtained and measured. The method of study and the precautions taken were the same as those previously described.

RESULTS

Table 1 summarizes the changes in the size of the heart and in the blood pressure of 18 myxedema patients as a result of treatment. Fifteen of the 18 patients had enlarged hearts, i e the transverse cardiac diameter was greater than half the internal diameter of the chest. The transverse diameter of the heart decreased in all but one instance, the decrease varying from 1.3 to 4.6 cm. The one patient, Mr H T, who failed to show a shrinkage in the size of the heart, had a normal sized heart before treatment, was suffering from angina pectoris and showed bundle branch block by electrocardiogram. He died suddenly at home a year later, probably as a result of coronary occlusion.

A few of the cases require special comment. The second teleroentgenogram in the case of Mrs E D showed the diaphragm to be one and a half spaces higher than in the premedication plate, and in the case of Mrs H E, one space higher. Since a high diaphragm causes the cardiac measurements to be too large, it follows that the actual shrinkage of the heart in these two cases was greater than that observed. In the case of Mrs J N the observed shrinkage was obtained after two weeks. Remeasurement of the heart five and one-half months later showed that the heart had returned to its original size. The reason for this probably lies in the hypertension persisting throughout this period. The patient, Mr J P, developed myxedema as a result of thyroidectomy for hyperthyroidism two months previously. The transverse diameter of his heart shrank after thyroid medication approximately to the size present before operation. This patient is exceptional in that he is the only one in either series who had rheumatic heart disease.

* Received for publication April 16, 1934.

¹From the Thyroid Clinic and Metabolism Laboratory of the Massachusetts General Hospital.

The various factors which may play a part in this cardiac shrinkage were discussed in the previous paper. The changes in blood pressure were of the same order as those in the previous series. Fourteen patients had electrocardiographic records made before treatment, and all of them showed some of the typical abnormalities found in myxedema. None of the patients showed evidence of congestive failure.

In our previous paper we mentioned the pathological changes in the hearts of five patients, examined post mortem, two of whom had not received any thyroid medication. Recently, we had the opportunity, through the kindness of Dr J H Townsend, to see a patient with myxedema, who died before treatment could be instituted. The heart in this case* was hypertrophied and the myocardium soft and friable. Histologically the muscle bundles and fibers and the connective tissue were widely separated by interstitial edema.

Two papers on this subject which appeared recently are worthy of mention. Hallock² reported two patients with myxedema, one showing gross congestive failure which disappeared under thyroid medication, and the other showing a diffusely dilated heart and a subnormal minute volume output, but no gross cardiac failure. No question can be made of the

* We are indebted to Drs H E McMahon and R Osgood for permission to mention the cardiac findings here. They will publish a complete pathological study of this case in the near future.

facts presented by this author, but we cannot agree that a diffusely dilated heart, accompanied by signs of dyspnea, or a decreased minute volume output are evidence of cardiac failure. We believe, rather, that they are part of the picture of myxedema. The paper of Ohler and Abramson³ concerns itself mostly with the electrocardiographic changes in myxedema. Thirteen of their 21 patients studied showed abnormal electrocardiograms. Cardiac enlargement occurred in seven of the patients with abnormal electrocardiograms, and in all but one the size of the heart diminished under thyroid therapy. However, their data do not warrant the conclusion that mild congestive failure is a frequent clinical finding. It is also difficult to explain why they get electrocardiographic abnormalities in only 62 per cent of their cases, whereas we get abnormalities in all of our cases.

SUMMARY

The changes in the size of the heart and in the blood pressure of 18 patients with myxedema under thyroid medication are presented to supplement the data of 30 patients previously reported. It appears to be characteristic of the heart in myxedema to be enlarged and to undergo appreciable shrinkage as the disease is ameliorated by the administration of thyroid substance. All of the electrocardiograms of these patients taken before treatment showed abnormalities. None of the patients showed congestive failure.

SMALL INTESTINAL INTUBATION EXPERIENCES WITH A DOUBLE-LUMENED TUBE *

By T. GRIER MILLER, M.D., F.A.C.P., and W. OSLER ABBOTT, M.D.,
Philadelphia, Pennsylvania

INTRODUCTION

THE small bowel, excepting the duodenum, has been less extensively and less satisfactorily studied than any other unit of the gastrointestinal system. Various explanations readily suggest themselves: its inaccessibility for direct investigation, the complexity and varied sources of its secretions, the difficulty of obtaining its contents, even in experimental animals, in a normal state of the organ, its elusiveness under the roentgen-ray, its relative immunity from disease. Our knowledge of its secretory and motor functions has rested almost entirely on animal experimentation, on chance observations at operation and on the study of the contents obtained after jejunostomies and ileostomies, methods which, nevertheless, have led to invaluable results.

Several workers^{1, 2, 3} have accomplished small intestinal intubation in man. McClendon and his associates,² in 1920, reported on the hydrogen ion concentration of the contents aspirated from two subjects, but their technic required four days for the tube to reach a level at most four or five feet below the pylorus. None of their methods has led to extensive investigation or important results. Recently, however, we⁴ have developed a technic that seems practical, and that, we believe, may eventually be applied in a more or less routine fashion.

PRINCIPLES OF THE TECHNIC

The passage of the tube along the bowel depends upon the attachment to its distal end of a collapsible rubber balloon which, when distended in the third portion of the duodenum, stimulates peristaltic waves that carry it down the intestinal tract (figure 1). The injection of substances into, and the aspiration of material from, the bowel is provided for by having the tube double-lumened: one lumen for distension and deflation of the balloon, the other, for injection and aspiration.

The tube may be introduced into the duodenum in the usual way or by manipulation under the fluoroscope according to Morgenstern's⁵ technic. By the latter procedure we have sometimes been able to have it enter the jejunum within three to five minutes. When the balloon, in the duodenum, is moderately distended with air under the fluoroscope it usually can be seen to rush immediately to the region of Treitz's ligament. Some massage over

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934.
From the Gastro-Intestinal Section of the Medical Clinic, Hospital of the University of Pennsylvania.

Aided by a grant from the Faculty Research Committee of the University of Pennsylvania.

that point commonly causes it to move slowly around the curve into the jejunum and then to rush 20 to 30 cm farther very quickly. Once the jejunum has been entered, we have found it practicable to allow the patient considerable freedom so long as he continues to swallow the tube at the rate of one centimeter per minute until its proximal end has nearly reached the mouth. At that time he should be re-fluoroscoped to make certain that no coiling of the tube in the stomach has taken place (figure 1)

The outside diameter of the tube is only 6 mm, but each lumen is slightly larger than that of the ordinary duodenal tube, the length which we have

FIG 1 Roentgenogram showing double-lumened tube with attached balloon in small intestine. Note characteristic curves of parts of tube in stomach and duodenum. One lumen of tube filled with 8 per cent sodium iodide solution, balloon partly filled with iodide solution, partly with air.

found suitable for reaching the ileum is nine to ten feet (270 to 300 cm), this allowing the tip easily to advance five to six feet (150 to 180 cm) beyond the pylorus. In one instance with only this length of tubing the balloon reached the middle of the transverse colon (figure 2). Only in that case did we have a balloon pass beyond the terminal ileum, yet when it passed as much as four or five feet below the pylorus it was always beyond the jejunum, because when a barium mixture then was injected no valvulae conniventes could be seen. Such intubation of the intestines has often required not more than three hours, and being accomplished in the morning has allowed the afternoon for experimental procedures.

We have introduced the tube into the small intestine for a distance of 100 cm or more in 75 persons, doing in all more than 100 intubations. At first we failed in about 50 per cent of the attempts, due chiefly to inability to traverse the pylorus within a reasonable time, but, since using the Morgens-tern technic, have been successful in fully 80 per cent. In no instance, with the balloon deflated, have we had any difficulty in removing the tube by mouth. Some of the subjects have been ward or out-patients, others, unemployed individuals to whom we paid small fees.

FIG 2 Roentgenogram showing double-lumened tube in stomach, duodenum, small intestine and large intestine to middle of transverse colon. Barium solution was introduced by tube after tip had reached the transverse colon, and none of barium appears in small bowel.

In making the aspirations the following method has been employed routinely: with the distal end of the tube at the desired level in the bowel, determined by the length of tubing swallowed and by fluoroscopic observation, the balloon is deflated, or it is allowed to remain only slightly distended in order to interfere with the escape of contents beyond the orifices of the collecting lumen. The proximal end of the aspiration lumen is connected with a syphon drainage system arranged to maintain constantly a negative pressure of 60 cm. of water and to allow the collections to be made, under oil, into glass receptacles that may be changed as desired (figure 3).

FIG 3 Longitudinal section of double-lumened intestinal tube with attachment to system for making collection of intestinal contents *A* indicates lumen used for aspiration, *B* lumen for inflation and deflation of balloon (1) 2, clamp on proximal tube connected with *B*, 3, perforations, 4 proximal tube connecting *A* with collecting system, 5, bottles partially filled with water (10) and connected by tube (11) so as to maintain constant negative pressure, 6, glass tube for collection of specimen, 7, specimen, 8 oil, originally injected into 4 and *A*, and now overlying specimen, 9, doubly perforated stopper

EXPERIMENTAL OBSERVATIONS AND COMMENTS

The fasting intestinal contents, under the conditions of the method, have come out in small spurts, often of only a few drops, sometimes a few cubic centimeters, with irregular intervals of minutes when no flow occurred. This has suggested the influence of peristaltic waves or of changes in the tonus of the intestinal walls bringing down the bowel small amounts of secretion at a time. Occasionally much larger amounts, 10 to 20 c c, have come through the tube in a continuous rapid flow. This, as demonstrated by introducing a dye into the stomach, has resulted from an unusually rapid passage of gastric contents to the balloon area. Under such circumstances the material collected has been more liquid, lighter in color and of a lower hydrogen ion concentration. Ordinarily the material collected under fasting conditions had the gross characteristics of duodenal fluid, being slightly cloudy, usually of a light yellowish or greenish color, sometimes dark green,

and changing after standing to a perfectly clear solution with a slight, semi-mucoid sediment. Occasionally, but only in achlorhydric individuals with a nasal discharge, small shreds of mucus with pus cells embedded in them have been encountered, but never of sufficient quantity to occlude the tube lumen. This would suggest that the presence of the tube does not lead to irritation of the bowel wall.

Under fasting conditions, with the balloon empty or moderately deflated, it sometimes required one to two hours to secure a specimen of 5 to 15 c c of material, and in 13 cases an average of only 33 c c per hour was obtained. Whether under such conditions very little gastric, duodenal and jejunal secretion occurs and little biliary and pancreatic secretion is ejected from the common bile duct or whether the secretions are largely absorbed as they pass down the jejunum and ileum has not been determined; doubtless both are factors in varying relationship.

In six subjects, when 150 to 450 c c of water had been administered by mouth while the tube was being swallowed, some of them taking most of it during the hour preceding the first collection, the average rate of flow through the tube was actually decreased to 22 c c per hour. Nevertheless, the chloride content in the specimens after the administration of water by mouth was often reduced, indicating that some dilution, probably with proportionate increase of absorption, had occurred. When to one subject 2 gm of decholin were given intravenously, no increase of flow was observed. When 0.5 c c of a 1:1000 solution of histamine was given subcutaneously to each of 10 cases no increase in the rate of flow occurred until the gastric secretion that followed the histamine injection reached the area from which the collection was being made, indicated by the presence in the specimen of vital red, which had been introduced into the stomach at the same time that the histamine was injected. Thereafter the average rate of flow was increased to 64 c c per hour. Also, in several instances, 100 c c of a 25 per cent glucose solution had no effect on the rate of flow until the sugar itself appeared in the specimen, then the average rate of flow was 82 c c per hour.

These observations seem to indicate that the normal content of the small bowel at or beyond the jejuno-ileal junction under fasting conditions is small in amount and that it passes down the tract at a relatively slow rate, that the administration of histamine subcutaneously has little, if any, immediate effect on the volume of the intestinal content, but that eventually, when the gastric secretion of higher acidity that follows the histamine reaches the drained area, a moderate increase in the amount and rate of flow of the intestinal contents occurs, and that a hypertonic glucose solution introduced orally produces a more marked increase in flow, but again only when the solution itself reaches the area of bowel under investigation.

The ultimate increase in the amount of contents after histamine and glucose is undoubtedly due, in part at least, to the added increment from the stomach, but also, since the acidity usually was not appreciably lowered, it is obvious that there occurs, in addition, an increased flow of alkaline material

from the pancreas and perhaps the liver. Although certain animal experiments recently performed in the Surgical Research Department of this University show that after histamine an increase of succus entericus develops in closed intestinal loops, the failure of an increased flow in our human cases until the gastric contents arrived would suggest that the increased flow of intestinal secretion is due to altered chemical conditions in the upper small intestine rather than to a direct action of the histamine.

An extensive study of the chemical nature of the small intestinal contents at various levels and under various conditions is being made in this Clinic by Abbott and Karr, and will be reported upon later. It may be said here, however, that, using a quinhydrone electrode the hydrogen ion concentration has been found in the neutral range (pH 6.6 to 7.3), whether pure fasting contents or material collected after the administration of histamine subcutaneously, decholin intravenously, or glucose or fats by mouth were studied. This is in agreement with the work of Mann and Bollman⁶ and of others on animals. The intestinal fluid maintains its tonicity with blood plasma under most experimental conditions, but it may apparently under certain special circumstances become hyper- or hypotonic temporarily. The tonicity is maintained primarily, according to Abbott and Karr's results, by a balance between the chlorine and carbonic acid anions. The fasting calcium and phosphorus are usually within the blood plasma range.

In regard to the motor function of the intestine Abbott has been able, by connecting the intestinal balloon to a recording apparatus, to secure tracings from the small bowel, and on one occasion from the colon, that indicate changes in pressure incident to the exhibition of certain drugs quite as successfully as they have been obtained in dogs with intestinal fistulae. Thus he has demonstrated nitrite inhibition of intestinal movements, the slower but more prolonged suppression of activity by atropine (figure 4), the increase of peristaltic activity following posterior pituitary extract and the effects of other drugs such as physostigmin and acetyl B methylcholin.

By removing the lateral wall from one lumen of the double tube for a certain distance above its distal end and attaching to the shortened lumen a second balloon it has been possible to secure simultaneous kymographic records from two known sections of the tract. Thus one balloon may be in the stomach or duodenum and the other in the jejunum or ileum at any desired distance from the pylorus.

Furthermore, it has been found practicable to give a subject a small barium meal and so to visualize the stomach and intestine while at the same time making kymographic records. In this way Abbott and Pendergrass have been able to show the effect of peristaltic activity, as recorded, on the intestinal contents, to separate increase in tonus from peristalsis, and to indicate the direction, whether upward or downward, of any particular peristaltic

wave Specifically, by this combined technic they have demonstrated that the gastric retention which follows the exhibition of morphine in man is due to an increased tonus of the muscular wall reaching its greatest intensity not in the pylorus but in the duodenum On several occasions they have observed the barium mixture advance farther than the cap, while a balloon in the portion of the duodenum through which barium was not passing was re-

FIG 4 Simultaneous tracings of respiratory rhythm and of duodenal and ileal contractions in a healthy intact human subject Balloons in duodenum and in ileum were attached respectively to the two lumina of double tube, and the ileal balloon was 160 cm below the pylorus Note inhibitory effect of 1/75th gr of atropine, injected subcutaneously, on the duodenum, and its less marked effect on the ileum

cording a prolonged spasmodic contraction They have been enabled by the kymographic records to determine when the enlargement of a segment of small bowel, as seen under the fluoroscope, is due to relaxation of tone and when it is due to forced distention by the passage down the bowel of intestinal contents By omitting the second or proximal balloon and by making continuous suction well above the balloon, they have studied the pressure changes in a segment of bowel independent of any contents coming down from above

CONCLUSION

Thus, we have referred to various experiences with a new method of studying the secretory and motor functions of the human small intestine to indicate the value of the technic, and have presented certain data that confirm results obtained previously only by animal experimentation It is believed that further experience will lead to simplification of the technic, making it available eventually for the study of pathologic conditions of the small bowel

We are indebted to Dr W G Karr, Chemist to this Clinic and Assistant Professor of Physiological Chemistry in this University, for the chemical examinations reported upon in this communication

DIAGNOSIS AND TREATMENT OF CERTAIN TYPES OF CHRONIC DIARRHEA *

By PHILIP W BROWN, M D , F A C P , *Rochester, Minnesota*

IN fully two-thirds of the cases of chronic diarrhea encountered at The Mayo Clinic there are no definite findings to explain the trouble. These patients usually have drifted from one place to another, have followed dietary fads, and have had the colon flushed. They constitute a puzzling group for both diagnosis and treatment.

There is a so-called harmless type of diarrhea which does not impair the patient's health, this may be present for years and the weight may be normal or even above normal, anemia is not present, and other laboratory studies give negative results. This type may be thought of as the "habit of diarrhea," similar to the "habit of constipation." It should be cared for on a sane, causal basis, and seldom necessitates medication. Of the number of people who lack free hydrochloric acid, it is surprising how few have diarrhea, even more surprising is the small percentage of those who receive benefit by taking acid.

The most common type of chronic diarrhea is that due to neurogenic or psychogenic factors, even in other types, the diarrhea seems to have its origin in shock or nervous upset. A lawyer may have a "running of the bowels" prior to a court trial, and a high-strung, nervous person may have diarrhea when under any emotional strain.

The term "colitis" is especially harmful when applied to this group, it is interesting and amusing to read of colitis as referred to in "The Story of San Michele," but it is another matter to treat patients after they have become obsessed with the idea of colitis. They search for the colitis specialist, the colitis serum, and the colitis diet. Certainly the term colitis should be reserved for cases in which inflammation of the colon is actually present. Some of these nervous people have diarrhea and constipation alternately. The relationship between irregularity of the bowel and nervous strain may not be as apparent as in the purely nervous group of patients. The patients should be instructed and educated in habits of living and eating, but should not be treated for colitis. Wholesome, simple meals, without excessive roughage, and a sane balance between work and play is the ideal program. Seldom is it fully realized, but much more is accomplished by striving for it than by irrigating, vaccinating, or dieting. The judicious use of mild sedatives is practically the only medication that should be considered. "Treat the patient, not the colon" would seem a wise motto.

It is obvious that the treatment of such cases must never be undertaken until all possible causes for the dysfunction of the bowels have been investigated. No matter how neurotic and hysterical the patient may be, the fail-

ure to recognize early carcinoma of the bowel, chronic ulcerative colitis, or hyperthyroidism will react most unfavorably on any physician who has diagnosed the trouble as "nervous" Such errors must occur occasionally, but no effort should be spared to rule out organic disease

I have reviewed the records of about 700 patients who have been examined in the past four years and whose condition was diagnosed as diarrhea of uncertain origin Many had acute intercurrent enterocolitis Psychogenic and neurogenic types of diarrhea were most common among the chronic cases But, in addition, three other, smaller but definite groups were observed In one group the condition seemed related to allergic phenomena, in one it was a sequel of an acute infection, and in the third the diarrhea was a prominent symptom of a deficiency disease (table 1)

TABLE I
Chronic Diarrhea

| | Allergic (34 cases) | Postinfectious (24 cases) | Deficiency (20 cases) |
|---|--|-------------------------------------|---|
| Etiology | | | |
| Incidence by sex | Equal | Equal | Females to males, 4 to 1 |
| Onset | Early life, after emotional stress | Following any acute infection | Insidious, dietary deficiency |
| Allergy (hives, hay fever and so forth) | Frequent | No | Occasionally |
| Symptoms | | | |
| Type of diarrhea | Sudden attacks or explosions | Steady or intermittent, watery | Large, bulky, gray, foul |
| General condition | Good | Good to fair | Fair to poor |
| Stomatitis, vaginitis, tetany | No | No | Common |
| Anemia | No | Seldom | Common |
| Treatment | | | |
| Diet | Adequate, elimination diets, keep a food diary | Adequate, low residue | High vitamin, high protein, low residue |
| Drugs | Soricin, calcium, sedatives | Iodine, dihydranol, vaccine calcium | Liver extract, calcium, parathyroid, iron |

ALLERGIC DIARRHEA

In bringing up the subject of allergy, one immediately invites criticism The enthusiast labels most of the cases of nervous diarrhea as allergic in cause, whereas those at the other extreme refuse to consider allergy unless the patient has a violent and prompt reaction following ingestion of a certain food Too much stress can be laid on allergic reactions, but when I re-

viewed this large group of patients with diarrhea, I noted that some patients had an inherent peculiarity which might contribute to the dysfunction of the bowel. Skin tests for sensitivity have not yet proved to be as valuable for ingested as for air borne substances, although the number of positive reactions to foods is increased by use of the intradermal method. Interpretation of results is difficult, partly because all allergic persons are high strung and emotional, although the reverse is not true. Again, it is puzzling to find that people become intolerant to foods formerly well tolerated. Perhaps acute infection or nervous depletion may antedate the explosion of what has been latent allergy. Some people begin to have hay fever in middle life, although they have lived in the same community for years.

I selected only 34 cases for study, because the data on them were adequate, and usually further information had been obtained. During the past four years, economic stress has made it difficult for many patients to remain away from their work for observation and treatment. What follows is based on these 34 cases although some of the statements are general and in the present tense.

In this small group of cases numbers of males and females were equal, and the average age was the late thirties. Most of the patients were aware of peculiar reactions, either hives, hay fever, or digestive upsets since early adult life, whereas nine of them stated they had always suffered from disorders which a physician would interpret as probably allergic. Twenty of the group had had the following allergic phenomena for five or more years: nine had migraine, five, urticaria, one, asthma, and five, hay fever. Allergy in the family was noted only in six cases. Six patients had probable allergic manifestations for one year or less, in four of these, fatigue, acute intercurrent infections, or mental stress seemed to have been precipitating factors.

That the condition may be allergic diarrhea is suggested by the history of rather sudden attacks of loose bowel movements which occur either during the day or at night. A third of the patients normally had loose bowel movements, with occasional attacks of diarrhea. The remainder of the group had the sudden, acute attacks that would last from an hour to several days. The foods which the patients considered factors in producing trouble were chocolate, clams, veal, pork, various fresh fruits and vegetables and fats. Milk was a known offender in five cases. Two patients were sensitive to iron and belladonna. A patient may state "Both my boys and I are scourged by veal and pork." Often the evidence for allergy must be inferred. If the general examination gives negative results, if the patient's weight and color are good, and if direct or indirect evidence of allergic reactions is present, the diagnosis is suggested. Some patients, either on their own initiative or on advice, have eliminated so many foods that they have lost weight and perhaps even have developed some deficiency. This may cause confusion, and caution must be exercised whenever a diet is prescribed.

Treatment This may be both specific and nonspecific. The former refers to omission of the offending foods from the diet. Often, these foods

are not known, and yet a physician dislikes to make a diagnosis of "just nervous diarrhea." It is hard to say why calcium helps some patients. Perhaps an excess supply of it may replace that lost in the stool, or again it may have a definite influence on the metabolism of muscle and nerve tissue. To influence the level of the blood calcium, it must be administered with the patient fasting. I prescribe one heaping teaspoonful of calcium lactate or tri-basic calcium phosphate in warm water three hours after meals, or two teaspoonfuls on arising and on retiring. Morris and Dorst's suggestion of soricin (purified sodium ricinoleate) has been followed in several cases, that is, prescribing a globule of 10 grains (0.65 gm.) to be taken with cold water half an hour before meals. It is still not understood by me what soricin accomplishes, and yet with its use alone or in combination with the calcium I have had gratifying results in several instances. Seven patients have been greatly benefited by this regimen, whereas four others felt that the soricin was of no value. Various regimens, such as calcium with soricin, with parathyroid given orally, with dihydranol or with sedatives have proved beneficial to 13 patients, whereas the condition of six others was not improved. In all instances, an effort was made to see that the diet was sufficient in all food elements. Occasionally, elimination diets, as first suggested by Alvarez, and later carefully worked out by Rowe, were advised but lack of time and funds usually necessitated the patients' following this plan at home. Vaughan recommended keeping a food diary, this is particularly valuable if the patient is intelligent and not too neurotic. Vaughan stressed that the patient must not note just "cheese or salad eaten," but what kind of cheese, the components of the salad, and the kind of oil used in the dressing.

Measures to improve the general physical and nervous stability are as important as drugs and diets. Recreation, work, stimulants, and frequently oral foci must be thoroughly considered. In two cases, the apparent intolerance to certain foods with associated diarrhea was greatly benefited by elevation of the low metabolic rate, soricin also was administered. Both patients insisted that occasional courses of soricin, added to maintenance of the metabolic rate at about minus 5 per cent, were essential to their good health.

POSTINFECTIOUS TYPE OF DIARRHEA

This term is applied to a group of cases in which diarrhea, either steady or intermittent, is a sequel of an acute infection, this may have been appendicitis with rupture, "intestinal flu," or "food poisoning." The actual initial infection is not always definite, and yet I was impressed by the records of 24 cases in which some acute episode had been followed by dysfunction of the bowel. These 24 patients had had diarrhea from three months to 15 years, with an average of about two years. Eleven of them had attacks of diarrhea, whereas 13 had more or less constant looseness of the bowels. Six of them had lost a little weight. Six had moderate secondary anemia, the patient with the anemia of lowest grade had 9.5 gm. of hemoglobin per 100 c.c. of blood. Patients of this group were more definitely

disabled than those of the allergic type. As a rule, the degree of anemia or loss of weight was proportionate to the dietary regimens which had been followed.

Treatment In view of the onset with infection, cultures of stools were made in nine instances, although there was no thought of identifying any organism which initiated the diarrhea months or years previously. Effort was directed toward obtaining the organisms which predominated and preparing a vaccine, as suggested by Dorst and Morris. Five patients considered that much benefit resulted, while four patients were not improved. Three patients were markedly improved following removal of infected tonsils or devitalized teeth. Removal of definite oral foci is always justifiable in any cases in which the cause of the diarrhea is indeterminable, although one should be conservative in promising definite results. Following the use of drugs, success has been none too good. Dihydranol, calcium, sedatives, soricin, parathyroid tablets, tincture of iodine, and inert powders are among the chief drugs that have proved helpful in different cases. One patient may be benefited by iodine, another may not, but is benefited by dihydranol, and so on. I tell such patients that a satisfactory regimen is usually evolved, but that I cannot plan, in advance, the individual program. Even more than in the cases of allergy, the personal and painstaking supervision of the patient is essential to obtain a good result. Seventeen of 24 patients stated months later that their condition was good, whereas the remainder were no better. Among the failures, I was impressed by the associated marked nervous exhaustion and occasionally psychosis. I still do not think that the unstable nervous system is the main factor in these seven cases, but as in other diseases, it is most important. Interestingly enough, five of these seven patients stated that their general health was now good although the diarrhea persisted, perhaps the "habit of diarrhea" had become established.

DEFICIENCY DIARRHEA

I think of this more as a syndrome, rather than a disease entity and of the diarrhea as one of the symptoms. It may be an involuntary type of deficiency as in nontropical sprue, or the voluntary type in which the patient has curtailed his food. If the patient becomes enmeshed in bizarre eating notions, such as faddist diets for ulcer, for diabetes, for colitis, or for purposes of reduction in weight, any of the previously named types of diarrhea may develop into deficiency diarrhea. I have seen severe states of depletion, with marked anemia, great loss of weight, diarrhea, and occasionally edema, which have developed from what seemed originally to be a nervous condition. Certainly it is a nervous diarrhea, but the patient eventually becomes seriously ill. Whether these syndromes of depletion are due to low intake of protein, or to loss of vitamin B, or to some other unrecognized factor, I am uncertain. I am not including cases of celiac disease or idiopathic steatorrhea.

In this group of cases of deficiency diarrhea, there were 20 patients, 16 of whom were women. In the other groups, the sexes were about equally involved. This is too small a group to permit any conclusion, but the preponderance of women is of interest. The average age was in the thirties, and the average duration of intestinal symptoms was about five years. The onset was insidious in half and abrupt in the remainder. Three patients had lost but little weight, whereas 17 had lost from 5 to 60 pounds (2.3 to 27.2 kg). Stomatitis, glossitis, and vaginitis occurred singly or in combination in 10 cases. The stools were watery, often large and bulky, grayish, and occasionally frothy. Cramping of the extremities was present in two cases, in one, it was severe enough to necessitate hospitalization and prompt intravenous injection of calcium. Analysis of gastric contents of four patients revealed no free acid, but administration of hydrochloric acid was of no value.

Secondary anemia was present as a rule. The average value for hemoglobin was about 11 to 12 gm per 100 cc of blood, although it was as low as 5.4 gm in one case. The erythrocyte count was lowered, with a tendency to a high color index. The leukocyte count tended to be low; the highest count in all the cases was 8,500, while in the majority of cases it was about 5,000. In two cases, in which tetany and edema were associated, the value for calcium was 5.6 and 7.0 mg per 100 cc of blood, the plasma proteins were 4.3 mg and 4.1 mg per 100 cc of blood.

Treatment I think success varies directly with the cooperation of the patient and the opportunity to follow each case. Individual treatment is imperative. Of these 20 patients, 12 later reported that they were well, five were improved, and the condition of three was unchanged. In three cases, vaccines from cultures of the stool were tried, were found helpful in one case and were of no value in two others. Calcium was beneficial in 11 cases. In four cases, calcium and parathyroid extract were effective. More recently in the severe cases, especially if anemia was marked, intramuscular injections of liver extract in conjunction with large doses of iron have proved of value. If ferric citrate increased the diarrhea, 4 to 6 gm daily of Bland's mass or 3 gm of reduced iron usually would be tolerated. Foreign protein in the form of intravenous injections of typhoid vaccine was of no value in one case. If depletion and exhaustion were severe, transfusions of blood speeded the convalescence. A diet high in vitamins, high in protein, and yet with minimal residue was instituted. On each tray would be two tablets of Harris' yeast, and 20 to 30 drops of haliver oil with viosterol, or 1 ounce (30 cc) of cod liver oil was given each day. Many of the patients were given anti-amebic treatment, either to ensure that amebic infection was not overlooked, or as nonspecific treatment. No benefit ensued from the use of these drugs.

Relapses are not uncommon. The patient must adhere to this general program for an indefinite period. Nervous shock or acute infection may

precipitate a relapse The margin of safety of these patients is low, and they need more protection than the average patient

CONCLUSIONS

1 The diagnosis of colitis should be reserved for cases in which actual inflammation is demonstrable

2 Neurogenic and irritable intestinal syndromes constitute the largest group of cases of chronic diarrhea

3 Certain persons have inherent peculiar reactions which probably produce or increase intestinal function This is called allergic diarrhea

4 Following any acute infection, diarrhea may develop and persist for months or years

5 As a result of voluntary or involuntary curtailment or omission of certain foods, a deficiency syndrome may result, with diarrhea a prominent symptom

6 Experiences in treatment of the patients in the foregoing groups have been recorded

7 These clinical experiences reveal the need of much investigation by the biochemist, the bacteriologist, and the physician

EDITORIALS

RELAPSING FEVER IN CANADA

IN 1933 Palmer and Crawford¹ reported six cases of relapsing fever which occurred in the summers of 1930, 1931 and 1932 in the Arrow Lake region of British Columbia. In two of these cases spirochetes were found in the peripheral blood. This constitutes the first report of the occurrence of relapsing fever in Canada.

In the United States the disease has been so seldom recognized in the last fifty years that to most physicians it is little more than a name recalled from student days. Knowing, as we do, that epidemics of the disease have always been associated with times of war and famine, we have perhaps been scarcely grateful enough that it played no part in the mortality from disease in our Army in the World War and that through these recent years of depression it has not broken out among our millions of destitute citizens. Yet it is far from being an extinct disease. It is endemic and at times epidemic in European Russia, Poland, Finland and the Balkan States. In Serbia there are said to have been more than 12,000 cases in the World War. It is prevalent throughout a large part of Africa. The Belgian troops in East Africa in the War suffered heavily. Outbreaks and sporadic cases occur in India, China, Manchuria, and the Dutch East Indies. Nearer home, foci of the disease have been found in Columbia, Venezuela, Panama, and Mexico. In the United States, however, Palmer and Crawford were able to find record of less than 20 reported cases since 1875.

Prior to 1875 the Eastern seaboard was subject to a number of outbreaks of relapsing fever. During the decade from 1842 to 1852 the disease was very prevalent in Ireland, Scotland and England. In June 1844 an emigrant ship from Liverpool landed 18 cases of relapsing fever in Philadelphia. Fifteen of these were studied by Clymer and described in his book on fevers. Similar emigrant groups ill with the disease were seen in New York in 1848 and 1850 and in Buffalo in 1850. In 1869, 1870 and 1871 occurred the only widespread American epidemic. The disease was very prevalent then in New York, and Austin Flint studied over 100 cases on the wards of Bellevue Hospital. In Philadelphia there were over 1,000 cases and scattered cases were seen in the City of Washington and in Maryland, New Jersey and Connecticut.

Though with our present knowledge of the mode of transmission of the disease we should now be in a position to defend our population against similar great epidemics, it cannot be said that it is yet clear why we have been spared further outbreaks since that of 1870.

The first advance in our knowledge concerning the etiology of the disease

¹ PALMER, J. H., and CRAWFORD, D. J. M. Relapsing fever in North America, with report of an outbreak in British Columbia, *Canad. Med. Assoc. J.*, 1933, *xxviii*, 643-647.

came in connection with the epidemic in Continental Europe which preceded and accompanied the American epidemic. In 1868 Otto Obermeier,² a prosector in the Charité Hospital in Berlin, observed a spirochete in the blood of patients during the febrile stage of relapsing fever, though he did not publish this finding until 1873. In the Berlin epidemic of 1872-1873 there were over 100 fatal cases in the Charité Hospital alone, and hence abundant opportunity had existed to repeat the earlier observations. Others speedily confirmed Obermeier's findings but such was still the opposition to the acceptance of the "germ theory" that this early evidence of the etiologic relation of a pathogenic organism to a known fever was for a long time disputed and somehow never was granted the importance it merited. The causal relation of the organism to the disease was more definitely established when Munch, Moczutkowsky (1876), and Metchnikoff (1881) had shown that the injection of spirochetal blood is followed by characteristic relapsing fever in normal human adults.

In 1877-1878 Carter proved that the disease could be similarly transmitted to monkeys. In 1890 Pasternatzky found that the spirochete could live for some time in the body of a leech which had fed on a relapsing fever patient. From this it was an easy step to Tictin's experiments which showed the presence of spirochetes in bedbugs which had fed on relapsing fever cases. Tictin was able to transmit the disease to monkeys by injecting the fluid from crushed infected bedbugs. Though Flugge in 1891 had suggested that the louse might be a carrier of relapsing fever, proof of this was not furnished until a much later date. Sergeant and his coworkers (1910-1911) and Nicolle and others (1912) infected monkeys with crushed lice which had been taken from cases of relapsing fever.

Another important advance in our knowledge of the disease occurred in 1904. For many years a fever of the East and West coasts of Africa, characterized clinically by well defined relapses and apparently due to the bites of ticks, had been known as African tick fever. In 1904 Ross and Milne found spirochetes in the blood of persons suffering with this disease, and Dutton and Todd confirmed that observation and showed that the organisms are transmitted by a tick, *Oimithodorus moubata*.

Since that time many other species of Argasine ticks of the genus *Oimithodorus* have been proved to serve as vectors of relapsing fever in various parts of the world. It has been shown moreover that a number of small animals may act as hosts to the parasite and so constitute a reservoir of the disease. From such animals the disease may be transferred to man by means of the tick as a vector. On the other hand, in epidemic relapsing fever transmission is probably direct from man to man by means of the louse or occasionally the bedbug. The relapsing fever of middle Europe and the Mediterranean littoral is of the louse-borne type, as is much of that of Asiatic countries. The African, Persian and Central American relapsing fever is for the most part carried by ticks.

² OBERMEIER, O. Vorkommen feinsten, eine Eigenbewegung zeigender Faden im Blute von Recurrenkrankheiten. Centrallbl. f. d. med. Wissensch., 1873, vi, 145-147.

Have we since 1875 been spared further epidemics of relapsing fever because of our relative freedom from lice, or merely because no epidemic strain of the organism has developed in our midst? Certainly in our larger cities there are facilities for the transmission of a louse-borne disease sufficient to bring about limited outbreaks were the infection once started. Control measures should, however, guarantee us against a serious epidemic. Perhaps greater interest attaches to the possible spread northward of the infection in animals and ticks, from those central American countries in which it is prevalent. Ticks of the genus *Ornithodoros* are well distributed over our Southwest, and small animals to serve as a host reservoir are not lacking. The occurrence of four cases of relapsing fever in Texas³ due to tick transmission shows that foci of infection already exist. In connection with the British Columbian outbreak, Hearle⁴ published some very interesting observations which suggest that ticks are often transported to points far outside their usual range by attachment to migratory birds. It seems reasonable to expect therefore that in the United States we shall from time to time see sporadic cases of this disease in those people who are exposed to tick bites and that the number of such human cases will be proportionate to the prevalence of spirochetosis in the host animals and in the tick vectors. There exists, as to modes of transmission, a striking analogy between the rickettsial diseases, typhus and spotted fever, and relapsing fever. The gradual spread of the tick-borne Rocky Mountain spotted fever to distant states may be paralleled by relapsing fever.

These facts concerning a rare disease are perhaps of some interest to the internist who may be called upon to recognize it. If he should desire to consult a careful clinical description of the disease he will find that its more recent literature will be of comparatively little help to him in that respect. It is devoted far more to etiology than to symptomatology. A clearer impression of the clinical physiognomy of relapsing fever can be obtained from those who observed the disease with no distracting interest in spirochetes, lice or ticks. No better description can be found than that contained in the masterly article by William Pepper⁵ based on the study and analysis of close to 200 cases seen in the wards of the Philadelphia Hospital during the epidemic of 1870.

VENEREAL DISEASE INFORMATION

FOR A NUMBER of years the U. S. Public Health Service has been publishing, for the information of physicians, health officers, and others, a monthly abstract journal known as "Venereal Disease Information." This

³ WELLS, B., and GRAHAM, G. M. Relapsing fever in Central Texas, Jr. Am. Med. Assoc., 1930, xcv, 1834-1835.

⁴ HEARLE, E. Vectors of relapsing fever in relation to an outbreak of the disease in British Columbia, Canad. Med. Assoc. Jr., 1934, xxx, 494-497.

⁵ PEPPER, W. Relapsing fever, in PEPPER, W., and STARR, L. A system of practical medicine, 1885, Lea Brothers and Co., Philadelphia, pages 369-433.

publication contains usually one original article on a subject of general interest in connection with the venereal diseases and numerous abstracts from the current literature pertaining to these diseases. In the preparation of this abstract journal more than 350 of the leading medical journals of the world are reviewed and abstracts made of the articles on this subject.

The cost of "Venereal Disease Information" is only fifty cents per annum, payable in advance to the Superintendent of Documents, Government Printing Office, Washington, D. C. It is desired to remind the reader that this nominal charge represents only a very small portion of the total expense of preparation, the journal being a contribution of the Public Health Service in its program with State and local health departments directed against the venereal diseases.

REVIEWS

Child Guidance Clinics A Quarter Century of Development By GEORGE S STEVENSON, M D, and GEDDES SMITH 186 pages The Commonwealth Fund, New York 1934 Price, \$1 50

Dr Stevenson, as a director of the Division on Community Clinics of the National Committee for Mental Hygiene, has presented an excellent review of the development of Child Guidance Clinics since the establishment of the first clinic in Chicago in 1909 Since the beginning of the movement over two hundred such clinics have been established in this country, and as is well said by the authors, "The Child Guidance clinic is an attempt to marshal the resources of the community in behalf of children who are in distress because of unsatisfied inner needs or are seriously at outs with their environment

Its service is rendered through the direct study and treatment of selected children by a team consisting of a psychiatrist (who is also a well trained pediatrician), a psychologist, and psychiatric social workers" Therefore, child guidance is essentially a medical problem, and the National Committee for Mental Hygiene has always attempted to keep this movement under medical control

No better comment can be offered than that made in the last paragraph of the book "The Child Guidance Clinic is more than a therapeutic agency It is a tool for synthesizing the most promising approaches to problems of behavior and personality in childhood, and for demonstrating the synthesis to the professions concerned with these problems It is a laboratory in which new leads may be found for the study of the child"

J L McC

Who Shall Survive? A New Approach to the Problem of Human Relations By J L MORENO, M D 437 pages Nervous and Mental Disease Publishing Co, Washington 1934 Price, \$4 00

The author presents what he calls sociometric case studies He states "A sociometric case study endeavors to give an accurate account how an individual or group grows and changes not as an individual or a group singled out but as a part of the community in which it is and not in metric relations only but through the widely ramified actual expressions of the interrelated subjects" There are many diagrams, percentage tables, and rather incomplete case histories The book runs to 437 pages The reviewer confesses it left him in a fog

J L McC

English-German and German-English Medical Dictionary Part I English-German By JOSEPH R WALLER, M D, and MORITZ KAAZT, M D 201 pages, 11×15 5 cm Franz Deuticke, Leipzig and Vienna 1934 Price, M 6—

The English-German part of this dictionary, by Dr Moritz Kaatz, was written as a companion volume to the German-English Medical Dictionary of Dr Joseph R Waller Brief yet reasonably complete for the more frequently used terms, this pocket-size dictionary should be useful to the student of medicine

M F L

Handbook of Physiology By W D HALLIBURTON, M D, and R J S McDOWALL, M B, D Sc vi+971 pages, 16 5×22 cm P Blakiston's Son and Co, Inc, Philadelphia 1933 Price, \$5 50

Halliburton's *Handbook of Physiology* has been considered for years as a valuable text for medical students In this thirty-third edition, Dr McDowall has fol-

lowed the general plan of Professor Halliburton and has presented the subject in a clear and concise manner

The introduction of blank pages at the end of each chapter, so that the student can make notes, is to be commended

It is to be regretted, however, that references to original research publications are lacking

F A R

The Cyclopedia of Medicine By GORGE MORRIS PILRSOL, B S, M D, Editor-in-Chief, and EDWARD L BORTZ, A B, M D, Assistant Editor To be complete in 12 volumes, 9 volumes published to date 19 × 26.5 cm F A Davis Company, Philadelphia 1931 Price, \$120.00

The first nine volumes of this monumental work have been issued and it is expected that the last three will be forthcoming within the next few months The editors have arranged under the alphabetic system articles dealing with the fields of general medicine, surgery, gynecology and obstetrics, and the chief specialties These subjects have been interpreted in a broad sense so as to include the underlying sciences on which our clinical knowledge is based Though the general arrangement is alphabetical the alphabetic system is not followed in the same sense as it is in the dictionary Many topics are dealt with under one main heading, and this heading only is placed alphabetically For example, the section on cardiovascular diseases extends for nearly 400 pages in Volume 3 and constitutes in itself a rather complete monograph on this subject In this same volume the article on the cerebrum and cerebellum takes up 150 pages Similarly in Volume 8 the section on the liver and biliary tract occupies 231 pages In Volume 6, 400 pages are devoted to hematology These will serve as examples In a sense, then, these volumes contain a group of longer sections on the chief fields of medicine, surgery and the specialties between which, according to alphabetic order, fall shorter articles on innumerable subjects

The chief sections are the joint production of a number of authors These authors have evidently been chosen with great care and in general may be said to be the leading authorities in the fields with which they deal To cite only a few at random from the section on hematology Rowntree on blood volume, Barcroft on hemoglobin, Peters on serum proteins, Blooi on lipides, Stadie on blood gases, etc To the reviewer's mind these long sections contributed by so many notable authorities constitute the greatest attraction of the encyclopedia

On the other hand it has not proved possible to confine all discussion of certain subjects under one heading For example, there is a section on the lungs but it deals with only certain diseases of the lungs and with lung surgery, while such subjects as pneumonia and emphysema are dealt with elsewhere under the alphabetic order It is evident that a careful General Index will be a necessity

One feature of the encyclopediac arrangement lies in the inclusion of articles on many special topics concerning which the average physician's collection of books would contain little or nothing Of this type are, for example, the careful articles on the causes of sudden death (37 pages), on deaf-mutism (12 pages), on immature and premature infants (38 pages), and many others The excellent and full treatment of ophthalmological, otological and dermatological topics is notable A serious attempt has been made to present in a brief form general reviews of the clinical sciences, under such headings as bacteriology, immunology, etc The various subheadings under metabolism, each written by an author who has made important contributions to the subject he is discussing, are a good example of the value of these sections The sections on pathological physiology are also very carefully done

In general the articles on the infectious diseases, while for the most part adequate, appear disproportionately short in comparison to the space accorded to less common

conditions Measles is dealt with in 13 pages and malaria in 16 Six pages are devoted to mumps, while the interesting article on monsters takes up 32 pages

There appears also to be an excessive amount of space devoted to drugs, and in certain instances at least the discussion of the therapeutic usages of the drug should be revised to accord with modern practice

The format of the volumes is excellent and the illustrations for the most part well reproduced, especially the cuts from drawings and photographs, which are used very freely Certain of the colored illustrations are valuable, others are more striking than instructive

The reviewer feels that the "Cyclopedia of Medicine" is a very valuable work and that for purposes of reference and general study it will prove an invaluable supplement to the library of any practicing physician The Chief Editor and his Assistant and Associate Editors have performed an immense task in selecting the distinguished contributors to these volumes and in putting through the press so rapidly the nine volumes so far issued The other volumes will be awaited with interest

M C P

COLLEGE NEWS NOTES

NOMINATING COMMITTEE FOR 1934-35

In accordance with the provisions of the By-Laws, President Jonathan C Meakins appointed on May 5, 1934, the following Committee on Nominations

Charles F Martin, *Chairman*, Montreal, P Q
Roger I Lee, Boston, Mass
William J Kerr, San Francisco, Calif
Charles H Cocke, Asheville, N C
Gerald B Webb, Colorado Springs, Colo

It is the duty of the Committee on Nominations "to nominate candidates for the elective offices, Board of Regents and Board of Governors The selection of nominees for the Board of Governors shall be made after due consideration of suggestions of members from the respective states, provinces or districts which will be represented by the nominees, if elected The list of nominees for President-Elect and for the first, second and third Vice-Presidents shall be submitted to all the Masters and Fellows of the College at least one month before the annual meeting, and the election of all nominees shall be by the members of the College at its annual business meeting This does not preclude nominations made from the floor at the annual meeting itself"

By-Laws, Article I, Section 3

COMMITTEE ON EXTENSION OF POSTGRADUATE EDUCATION

F M Pottenger, *Chairman*, Monrovia, Calif
J H Musser, New Orleans, La
Luther F Warren, Brooklyn, N Y
Ernest B Bradley, Lexington, Ky
Walter L Bierring, Des Moines, Iowa

The above Committee has been appointed by President Jonathan C Meakins in accordance with the following resolution adopted at the meeting of the Board of Regents April 20, 1934

"*Resolved*, that the President appoint a Committee to investigate the advisability of and to formulate plans for the closer organization and greater cohesion of our members in their particular communities or states, such as done by the American College of Surgeons through their sectional meetings, with the object of carrying extension postgraduate medical educational facilities to physicians in more remote locations, and to bring back a report at the next meeting of the Board of Regents"

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following donations by members to the Library of the College by the authors

Dr Logan Clendenning (Fellow), Kansas City, Mo—1 book, "Behind the Doctor",

Dr Mark Gerstle, Jr (Associate), San Francisco, Calif—1 book, "The Doctor Discusses Your Questions",

Dr S Calvin Smith (Fellow), Philadelphia, Pa—1 book, "That Heart of Yours",

Dr Felix Cunha (Associate), San Francisco, Calif—6 reprints,

Dr Merle Q Howard (Fellow), Wauwatosa, Wis—1 reprint,

Dr Cole B Gibson (Fellow), Meriden, Conn—2 reprints,

Dr Martin J Synnott (Fellow), Montclair, N J—1 reprint,

Dr William F Wegge (Fellow), Milwaukee, Wis—1 reprint,

Dr Joseph Wiener (Associate), Asbury Park, N J—1 reprint,

Dr David O N Lindberg (Fellow), Decatur, Ill—6 reprints,

Dr Hyman I Goldstein (Associate), Caniden, N J—2 reprints

DR JAMES S MCLESTER HONORED

Dr James S McLester (Fellow), for many years a Regent of the American College of Physicians and a member of many important Committees of this organization, was selected as President-Elect of the American Medical Association at the last annual meeting of that Association at Cleveland

Dr Walter L Biering (Fellow and Regent of the College) was installed as President of the American Medical Association at the same session

The Board of Trustees of the University of Pennsylvania recently created a second professorship of medicine and elected Dr O H Perry Pepper (Fellow) to fill it This is the first time in the 169 years of the history of the Medical School of the University of Pennsylvania that there has been provision for more than one professor of medicine Dr Alfred Stengel (Master), present professor of medicine, has been a member of the medical school faculty for 41 years, and although he has reached the age of retirement will continue for a period of three more years through an extension requested by the Trustees

Dr Frederick G Banting (Fellow), for the past 11 years Professor of Medical Research at the University of Toronto School of Medicine, in recognition of his discovery of insulin, was knighted by King George of England on June 3

Dr Samuel E Munson (Fellow), Springfield, Ill, addressed Perry and adjoining County Medical Societies June 8, on the subject of amebiasis Dr Munson, who has served as Councilor for the Fifth Councilor District of the Illinois State Medical Society for the past nine years, was reelected for three years at the annual meeting of that society, held in Springfield, May 15 to 17

At the sixty-seventh annual session of the Mississippi State Medical Association at Natchez, May 8 to 10, the following members of the College contributed papers *Fellows* Dr W S Leathers, Nashville, Tenn, Dr Henry Boswell, Sanatorium, Miss, Dr William Krauss, Meridian, Miss, Dr James S McLester, Birmingham, Ala, and Dr G W F Rembert, Jackson, Miss *Associate* Dr Guy C Jarratt, Vicksburg, Miss

Dr Howard L Hull (Fellow) has resigned, effective July 1, as superintendent and medical director of Oakhurst Sanatorium, Elma, Washington, and has established an office in the Larson Building, Yakima, Washington, where he will enter private practice restricted to diseases of the chest Dr Hull was in charge of Oak-

hurst Sanatorium since September 1, 1923 His successor is Dr Leslie P Anderson of White Haven, Pa

Dr Lea A Riely (Fellow and Governor for Oklahoma), Oklahoma City, as a guest of the Section on Medicine and Diseases of Children of the State Medical Association of Texas, delivered two addresses, "Diabetic Problems" and "The Diabetic Child," before the sixty-eighth annual session of the society at San Antonio, Texas during the week of May 15

Dr Bernard L Wyatt (Fellow) and the Wyatt Research Foundation is erecting in Tucson, Arizona, an ultra-modern building to house the Wyatt Clinic The activities of the Clinic will be restricted to the field of arthritis

Dr D F Milam (Fellow), of the Rockefeller Foundation, New York City, has been assigned work in the Republic of Panama, and will be in Panama City for some months

Dr David Riesman (Fellow), Philadelphia, was the guest speaker at the 59th annual banquet of the Alumni Association of the School of Medicine, University of Cincinnati, on June 14 His subject was "Medical Progress in One Generation"

Dr Harold G F Edwards (Fellow), Shreveport, La, addressed the Texas State Medical Association, San Antonio, May 15, on "Radiation Therapy in Malignant Diseases"

Dr Hyman I Goldstein (Associate), Camden, N J, read a paper on "Hemorrhagic Blood Dyscrasias" before the New Jersey Medical Society at its 168th annual session, Atlantic City, June 6

Dr L F Barker (Fellow), Baltimore, read a paper on pneumonia before the same society on June 7, and the paper was discussed by Dr Goldstein and Dr Robert Kilduffe, of Atlantic City

Dr Ross V Patterson (Fellow), for several years dean of the faculty of the Jefferson Medical College of Philadelphia, was recently appointed by the Board of Trustees of that institution as professor of therapeutics The Alumni Association of Jefferson Medical College, at its 109th dinner early in June, presented the College with a bust of Dr Patterson

Dr James E Paullin (Fellow), Atlanta, Ga, was elected President-Elect of the Medical Association of Georgia at the recent annual session of that society at Augusta

At the unveiling of the portrait of the late Dr D Bushrod James, former Professor of Gynecology at the Hahnemann Medical College, on April 20, Dr James M Anders (Fellow) made an address, representing the medical profession not connected with Hahnemann Medical College or Hospital

Dr James K Hall (Associate) and Dr Beverley R Tucker (Fellow), both of Richmond were elected President and Vice-President, respectively, of the recently organized Section on the History of Medicine of the Richmond Academy of Medicine

Dr Paul D White (Fellow), of Harvard Medical College, Boston, recently delivered an address on heart disease to physicians of central Florida, under the auspices of the Orange County (Fla) Medical Society

Dr J O Elrod (Fellow), Forsyth, Ga , has been elected Vice-President of the Monroe County (Ga) Medical Society for the coming year

Dr Louis Hamman (Fellow), Baltimore, Md , is a Vice-President of the Medical and Chirurgical Faculty of Maryland for the coming year

Dr Robert A Peets (Fellow), Colfax, Calif , was elected President-Elect of the California Medical Association at its annual meeting May 2

Dr Samuel E Thompson (Fellow), Kerrville, Tex , was inducted as President of the State Medical Association of Texas at its annual meeting May 17

The Seventh Annual Graduate Fortnight of the New York Academy of Medicine will take place October 22 to November 2, 1934 The program will be devoted to diseases of the gastrointestinal tract Among Fellows of the American College of Physicians who will present subjects are

Dr Harlow Brooks, New York, N Y
 Dr A C Ivy, Chicago, Ill
 Dr W McKim Marriott, St Louis, Mo
 Dr Charles F Tenney, New York, N Y
 Dr Arthur F Chace, New York, N Y
 Dr William W Herrick, New York, N Y
 Dr Walter A Bastedo, New York, N Y
 Dr Thomas T Mackie, New York, N Y

Dr B S Pollak (Fellow), Medical Director of the Hudson County Tuberculosis Hospital and Sanatorium, Secaucus, N J , has been appointed one of three to represent the United States at the Ninth Conference of the International Union Against Tuberculosis, to be held in Warsaw, Poland, September 4 to 6, 1934 He will discuss Professor Leon Bernard's paper on "The Use and Organization of Tuberculosis Dispensaries"

Dr C J Tidmarsh (Associate), formerly of Montreal, is now connected with the Lahey Clinic, Boston

Dr William H Walsh (Fellow), Chicago, assisted by Dr Clarence O Sappington, recently completed a survey of the Health Department of the City of Buffalo, upon the request of the Board of Health and the approval of the City Council of that City

Dr J A Myers (Fellow), Professor of Medicine at the University of Minnesota, and Dr S A Slater (Fellow), Superintendent of the Southwestern Minnesota Sana-

torium, Worthington, have been elected Directors of the National Tuberculosis Association for the coming year

Dr Kennon H Dunham (Fellow), Cincinnati, Ohio, has been elected President of the National Tuberculosis Association for the coming year

Dr Louis H Roddis (Fellow), Commander (M C), U S Navy, is Editor of the U S Naval Medical Bulletin

Dr J W Torbett (Fellow), Marlin, Texas, was a delegate to the Texas State Medical Association at its recent meeting in San Antonio, and read a paper on "Our Biological Defenses or How Nature Cures"

OBITUARIES

DR CLAUDE EDWARD CASE

Claude Edward Case, of Clifton Springs, N Y, died at Doylestown, Pa, on January 27, 1934, of lymphosarcoma. Dr Case was born at Doylestown in 1893 and received his early education in the public schools there. He attended the medical department of the University of Pennsylvania from which he was graduated in 1917. After serving an internship in the Philadelphia General Hospital he became a lieutenant in the Medical Corps of the United States Army and was stationed at various American camps during the World War. Following his discharge from the army he associated himself with the health service of Cornell University at Ithaca and became Assistant Professor of Hygiene. In 1927, Dr Case joined the staff of the Clifton Springs Sanitarium and Clinic. He was a member of Phi Chi medical fraternity, the New York State Medical Society, and the American Medical Association, and on February 10, 1930, he was made a Fellow of the American College of Physicians.

During recent years Dr Case was particularly interested in the relation of radiology to internal medicine and published several papers in that field. He was known as an unusually kindly physician, one to whom his parents were devoted. For recreation he enjoyed golf and was an accomplished pianist. Dr Case is survived by his widow, Emily Radcliffe Case.

DR WARREN B STONE

Dr Warren B Stone (Fellow), Schenectady, N Y, died March 31, 1934, following a stroke.

Dr Stone was born in Lynn, Mass, in 1876. He received his medical training at Harvard University Medical School, from which he graduated in 1899. Thereafter, he served as intern for a year and a half at St Luke's Hospital, New Bedford, Mass, and then sought postgraduate study at the University of Berlin. He also did postgraduate work at Albany Medical College and Union University. In 1916, he became Head of the Ellis Hospital Pathological Laboratory. During the World War, Dr Stone was commissioned a Captain, but his services were retained in this country rather than abroad, due to his work in controlling the influenza epidemic. It is said that a serum developed by Dr Stone at the Ellis Hospital was very effectively used in controlling the spread of influenza, and that only 1 per cent of the 25,000 to whom the serum was administered contracted the disease.

At the same time that Dr Stone held the position as Head Pathologist of the Ellis Hospital, his ability was also recognized by the county authori-

ties, who made him head of the county pathological work. This laboratory, under his effective administration, became one of the divisional laboratories of the State Department of Health. In 1923, Dr. Stone resigned from his post at the Ellis Hospital to devote his full time to practice and consultation work. He fitted out a private diagnostic laboratory in his home with all modern equipment. During the past two years, he also did the pathological work at the Glenridge Sanatorium. He was also Examiner in Serology for the Civil Service Commission of the City of New York.

Dr. Stone was a past president of the New York State Pathological Society, a member of the Schenectady County Medical Society, the New York State Medical Society, the New York State Society of Pathology and Public Health, and had been a Fellow of the American College of Physicians since 1916.

DR. ADDISON E. ELLIOTT

Dr. Addison E. Elliott (Fellow) of San Diego died April 9, 1934. Dr. Elliott was ill last January with a pulmonary edema for a couple of weeks, recovering from that he worked practically all the time until two days before death occurred.

Dr. Elliott was born in 1875. He received his medical education at Rush Medical College. The first years following were spent in Chicago. About 1914 Dr. Elliott moved to El Centro, California, where he built up a good diagnostic and surgical practice. At a period after the War Dr. Elliott gave up his other work for roentgenology, in which he had been interested for many years, and went to San Diego. Following a year's work in roentgenology at the San Diego County Hospital he became associated with Dr. Lyell Kinney, with whom he carried on in the active work of roentgenology until his death.

Dr. Elliott was made a Fellow of the College in 1930. He was at one time President of the University Club and had been Chairman of the Council of the San Diego County Medical Society, and President of the San Diego Academy of Medicine, in addition to having memberships in other scientific organizations.

Dr. Elliott was a kindly man. He had no malice in his heart but thought kindly of all worthy men. He went out of his way to do acts of kindness that endeared him to all with whom he came in contact. Though he was modest and by nature moderately reticent he took his responsibility as it came to him, meeting his problems with clear decision. He had many friends in the profession in California. In San Diego, his home, he was loved as are all kindly, able men. His death was a loss to the profession and his community.

EGERTON L. CRISPIN, M.D., F.A.C.P.,
Governor for Southern California

DR HENRY GREEN

Dr Henry Green of Dothan, Alabama, an Associate of the College, died, after a short illness, on February 22, 1934, of cerebral hemorrhage

Dr Green was born in 1867 and received his M D degree from the University of Alabama School of Medicine in 1892 He practiced in Dothan, Alabama, up to the time of his death Dr Green was past President of the Houston County Medical Society and also of the Medical Association of the State of Alabama For many years Dr Green did a very large practice in his community

He was beloved as a physician and admired as a man He was honest, high-minded, intelligent, and sympathetic In his private life, as well as his professional life, Dr Green was an ideal citizen He was active until about two days before his death and his passing is a loss to the American College of Physicians as well as to the medical profession

FRED WILKERSON, M D , F A C P ,
Governor for Alabama

BILIARY DYSKINESIA *

By A C Ivy, Ph D, M D, F A C P, and PHILIP SANDBLOM, M S,
Med Lic, Chicago, Illinois

THE trend of modern medicine toward the early diagnosis of disease has led to an increased interest in functional disturbances which may precede or even cause organic changes in structure

In applying this viewpoint to the extrahepatic biliary passages, one may think theoretically of three kinds of functional disturbances, namely, of absorption, of secretion and of motility. Of these, we propose to discuss the disorders of motility or the so-called *biliary dyskinesia*, which may produce biliary stasis and the symptoms of gall-bladder distress or colic in the absence of calculus or inflammation. We shall give only a brief summary of the historical development, the physiologic basis and importance of this subject and point out certain pertinent observations we have made in our laboratory studies of the biliary tract.

Apparently the first clinical reports of gall-bladder colic without stone or infection were made by Krukenberg¹ in 1903 and Borghi² in 1913. These reports provided no explanation and attracted no attention. Undoubtedly many physicians have seen patients who have suffered gall-bladder distress without detectable anatomic cause and have explained the condition as being due to adhesions or to the passage of inspissated bile.

In 1909, the pathologists, Aschoff and Bacmeister³ laid the foundation for further development of the concept of biliary dyskinesia by describing what they called the "stasis gall-bladder." They distinguished two kinds of "stasis gall-bladder," the hypertrophic and atrophic, in which either hypertrophy or atrophy of the wall, especially of the muscle layer, was found in the absence of inflammation or stone formation.

In 1920, Schmieden⁴ in his important work on the "stasis gall-bladder" correlated the pathological with the clinical findings. He called attention particularly to those patients with typical gall-bladder distress in whom the surgeon at operation finds a markedly distended gall-bladder without calculus or inflammation. He thought that the distention of the gall-bladder was the cause of the distress, and that the distention was due to a mechanical

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934.
From the Department of Physiology and Pharmacology, Northwestern University Medical School.

hindrance to the flow of bile from the gall-bladder into the cystic duct. He thought the hindrance was due to an anatomical defect such as a kink, at the junction of the neck of the gall-bladder and the cystic duct (also see Rhode⁵). As is well known, this work was at first accepted with enthusiasm and later subjected to criticism because the hypothetical anatomic hindrance could not always be found.

In the meantime John Beig, the Swedish surgeon, was working on the problem and in 1922 he⁶ suggested that a functional disorder of the biliary passages might be the cause of biliary stasis. This suggestion was supported by his observation of an accompanying hypertrophy of the muscle surrounding the ampulla of Vater. This hypertrophy has also been observed by Westphal,^{13,14} Nuboer⁷ and Newman⁸. Giordano and Mann⁹ have also found hypertrophy of the common duct sphincter in some cases of cholecystitis and peptic ulcer. Nuboer⁷ has reported that the sphincter muscle is found to be hypertrophied in dogs 16 months after cholecystectomy and Westphal¹⁴ has made a similar observation. Before this, however, Oddi,¹⁰ in his classical work, and Meltzer¹¹ (1917) on the basis of physiologic theory had suggested that spasm of the sphincter of the ampulla may be the cause in some patients of biliary colic or icterus (also see Lyon¹²).

The concept of a "functional" cause of gall-bladder stasis has been especially developed and emphasized by Westphal,^{13,14} who, as a result of his experimental and clinical observations, classified and gave a general clinical description of the different types of biliary dyskinesia, their diagnosis and treatment.

Because Westphal's¹³ experimental work on the guinea pig and rabbit led him to produce the first clear-cut classification of biliary dyskinesia, we shall briefly give an account of his observations. It should be pointed out, however, that his observations have not been fully confirmed. (For a review of literature, see Ivy¹⁵). Westphal regards the sphincter of Oddi as being composed of two parts, possessing a different structure and function. The first part consists of a proximal muscular coat which surrounds the antrum beginning at the junction of the duct with the ampulla. The second part consists of a distal group of muscle fibers which surround the papilla. The work of Lueth,¹⁶ which the senior author observed, indicates that this view is probably correct. Westphal reports that when the vagus nerve is stimulated below the diaphragm with a weak current, the gall-bladder contracts, the antral portion of the sphincter manifests peristaltic movements and the papilla relaxes. He views this as being the normal type of response. With a stronger current, he reports that the tone of the gall-bladder is increased, and the movements of the ampulla are very lively. He suggests that this would cause a very rapid emptying of the gall-bladder, which, when it occurs in the human, he calls "hypermotile dyskinesia". When the vagus is stimulated with a still stronger current, he reports that the antral sphincter is thrown into spasm along with the contraction of the gall-bladder. This, he interprets, would cause spastic distention with pain, a condition he calls

"hypertonic dyskinesia" The difference between hypermotile and hypertonic dyskinesia is only one of degree of hypertonicity, and both are grouped under the general heading of "hyperkinetic dyskinesia"

On the other hand, when the splanchnic nerve is stimulated, Westphal reports that the gall-bladder and antral portion of the sphincter relax while the sphincter of the papilla contracts. This, he believes, would cause an atonic distention without much pain, a condition which he calls "atonic dyskinesia"

WESTPHAL'S CLASSIFICATION OF BILIARY DYSKINESIA

I Hyperkinetic

a Hypermotile Increased motility of gall-bladder and ampulla with rapid emptying

b Hypertonic Contraction of the gall-bladder against spasm of the sphincter with *spastic distention* and colicky pain

II Atonic Relaxation or atony of the gall-bladder with spasm of the sphincter of the papilla causing *atonic distention* of the gall-bladder with mild, continuous, "heavy," aching sensation

Lyon¹⁷ has classified the motor dysfunction of the extrahepatic passages into two types, "spastic dysfunction" and "atonic dysfunction," and suggests that in the course of time a spastic sphincter may cause the gall-bladder to become atonic. Smithies¹⁸ has referred to the condition as "physiologic block," and Schmieden¹⁹ has used the term "cholepathia spastica." Newman⁸ has used the terms "spastic distention" and "atonic distention," and cautions against the division of dyskinetic states into hard and fast entities. We agree with Newman's caution.

In regard to this concept, which maintains that biliary distress may result from a motor dysfunction of the extrahepatic passages, two pertinent questions present themselves for answer. First, can the sphincter of the common duct, or the choledocho-duodenal mechanism, contract with sufficient force to prevent evacuation of the contracting gall-bladder? And, second, is it possible for the resulting pressure to produce pain in non-inflamed biliary passages?

In answer to the first question, only evidence obtained from lower animals is available. In the dog it is established that the gall-bladder may contract with a maximum force of about 30 cm. of bile pressure, which is also about the secretory pressure of bile, whereas the common duct sphincter, or the choledocho-duodenal mechanism, may contract and exert a resistance of as much as 80 cm. of bile pressure¹⁵. Thus, it is evident in the dog that a spastic choledocho-duodenal sphincteric mechanism may cause an intra-biliary passage pressure sufficient to block the flow of bile either from the gall-bladder or liver.

In answer to the second question, experimental evidence obtained from normal human subjects by utilizing two different methods for gall-bladder excitation is available.

First, by pilocarpine, a parasympathetic excitant Westphal¹⁴ passed a duodenal tube and initiated gall-bladder evacuation with olive oil. He then injected a relatively large dose of pilocarpine, a drug which in the dog causes gall-bladder contraction with some filling of the cystic duct but no evacuation due to contraction of the common duct sphincter. After the pilocarpine injection, he observed that the flow of bile into the duodenum ceased, following which gall-bladder distress was frequently obtained. This distress was promptly relieved by atropine which abolishes the action of pilocarpine on the gall-bladder and sphincter.

Second, by cholecystokinin, a hormone agency which acts chiefly by direct action on the musculature of the gall-bladder During the past year, the senior author with Voegtlin and Greengard²⁰ has been studying the effect of secretin-cholecystokinin injections on the duodenal secretions in normal human subjects. The plan of the procedure is briefly as follows. The duodenal tube is passed. A number of control samples are obtained. Then a solution containing secretin and a little cholecystokinin is injected intravenously to determine the effect on the volume and chemistry of the duodenal contents. This injection generally produces a copious flow of both pancreatic juice and bile. In one of the first subjects, the following observations were made. After passage of the tube into the duodenum, a flow of bile-stained fluid was first obtained. Then the flow of bile-stained fluid ceased. Apparently a contraction of the common duct sphincter had resulted, shutting off the flow of bile. No distress was experienced at this time. Then the secretin-cholecystokinin solution was injected. A copious flow of pancreatic juice resulted which was not stained with bile. About 10 minutes later, right hypochondrial distress was experienced which gradually became more severe and finally was felt beneath the right scapula. After about 50 minutes, the distress was so severe that relief was sought. It was decided to ascertain if relief might be obtained by the introduction of magnesium sulphate. This was done and a few minutes after the introduction of the magnesium sulphate into the duodenum, the distress subsided and after seven minutes, dark bile was obtained from the tube. Cholecystographic evidence on this subject proved that the gall-bladder concentrated and evacuated normally. The duodenum and stomach were normal. Out of 19 normal subjects studied to date, biliary tract distress has been observed in three under these experimental conditions. This, we believe, constitutes a striking confirmation of Meltzer's¹¹ hypothesis that magnesium sulphate placed in the duodenum may relax the abnormally contracted sphincter of the common bile duct.

Until these observations were made, we were skeptical concerning the claim that pain can be produced in the non-inflamed biliary passages by such relatively low pressures as may be produced by the contraction of the gall-bladder. We were skeptical in this regard because Schrager and Ivy⁴³ had found in the dog that the minimal pressure required to elicit pain by distending the gall-bladder was 54 cm. of water, and by distending the bile

ducts 27 cm of water. However, it is to be noted that the pressure required to elicit pain from the bile ducts in the dog is just about the secretory pressure of bile and the maximum force of gall-bladder contraction. Also, Ivy and Oldberg²¹ observed pain distress with nausea and vomiting in a dog with the cystic duct occluded following the injection of cholecystokinin. Von Bergmann²² has observed that the injection of dehydrocholic acid, which stimulates the formation of bile, into patients with common duct stenosis causes pain. This evidence and our observations on man cited above have convinced us that pain may be elicited from non-inflamed biliary passages by the maximum pressure that may occur in their lumen, provided the pressure is raised rather rapidly, especially in the presence of a tonic musculature.

According to the German school, biliary dyskinesia is due to an abnormal parasympathetic or sympathetic innervation. Newman⁸ and Lyon¹⁷ are inclined to the view that there are constitutional factors which predispose to either of the two types of dyskinesia. Boyden²³ describes three types of responses of the normal human gall-bladder to stimuli, which appear to depend primarily on how the sphincter responds, but has not attempted to relate these types to predisposition to dyskinesia.

In regard to the etiology of this condition, we believe that one must not neglect to consider the duodenum, the tone and motility of which is closely related to the functioning of the common duct sphincter^{16, 24}. For example, Cram and Walsh²⁵ have demonstrated that experimentally induced duodenitis delays evacuation of the gall-bladder, and Shapiro and Kasabach²⁶ have found that a partial duodenal obstruction may also delay gall-bladder evacuation.

Most students of the subject of biliary dyskinesia, as we have indicated above, would place the cause of the functional obstruction solely at the site of the common duct sphincter. However, another possible site should be considered, because it is possible that a sphincter may be located at the junction of the neck of the gall-bladder with the cystic duct. Whether such a sphincter, which has been called the "collum-cysticus sphincter," exists anatomically, is disputed¹⁵. Lutkens²⁷ from Aschoff's laboratory, reports that he was able to find such a sphincter in 75 per cent of human subjects. Certain physiologic evidence submitted by Volborth²⁸ and Potter and Mann²⁹ suggests the existence of such a sphincter. Westphal¹⁴ claims that such a sphincter is present in dogs and derives its motor innervation from the vagus. Careful cholecystographic study in man should in the course of time provide an answer, because, if the "collum-cysticus" sphincter is spastic, the gall-bladder when excited should manifest annular bands of contraction without the expulsion of contents resulting. Whereas, if the common duct sphincter is spastic, the gall-bladder should expel contents and the hepatic ducts become visualized. Both have been reported to occur in dyskinesia patients³⁰⁻³³.

The concept of biliary dyskinesia, which we believe to be established, not only provides an explanation for the "stasis gall-bladder" of Aschoff,

but also provides a mechanism with which to visualize the cause of stasis which predisposes to infection and stone formation. When this is more widely appreciated and recognized, it is not unlikely that the incidence of cholelithiasis, particularly in pregnancy, may be reduced by appropriate prophylactic therapy. The literature on the relation of pregnancy to the evacuation of the gall-bladder is meager (Ivy¹⁵). Westphal^{13,14} and Kalk and Schondube³² made observations which led them to believe that a hyperkinetic dyskinesia was present in early pregnancy. (See also references 23 and 34-39.) But a large series of patients has not been studied. This obviously important topic needs investigation.

This concept also provides a rational basis for gall-stone colic without gall-stones, for so-called "cholecystitis" with a normal gall-bladder at operation, and for so-called "hepatic neuralgia." It is further possible that the presence of an irritable or hypertrophied sphincter of the common duct may explain the recurrence of symptoms in some patients following cholecystectomy. The early relief would be due to the temporary paralysis of the sphincter that always follows cholecystectomy. But, after recovery from the temporary paralysis, the irritable or hypertrophic sphincter may again produce symptoms of biliary tract distention. The recognition of this possibility should emphasize the importance of the medical rather than the surgical management of these patients, although it must be recognized that some dyskinesia patients are benefited by cholecystectomy and some patients with residua after cholecystectomy are benefited by choledochoduodenostomy. In this connection, Aschoff⁴² reports a series of 215 cases in which 25 stone-free gall-bladders were removed, of the 25, seven had residual symptoms accountable for only by dyskinetic processes. (See also reference 40.) It is likely that the number of discouraging results may be fewer when the idea of a functional disturbance is better understood and managed therapeutically by the surgeon and internist.

As indicated in the introduction to this paper, we did not propose to discuss the diagnosis and treatment of biliary dyskinesia. (For discussion of diagnosis and treatment, the reader is referred to the following references 8, 13, 14, 17, 19, 22, 30, 31, 32, 33, 40.) We should state, however, that we do not believe the diagnosis to be simple. The presence of pain in the gall-bladder region with a normal 14 hour cholecystogram and absence of clinical evidence of an inflammatory process may lead one to suspect but not diagnose a dyskinesia. In this paper we have desired only to emphasize that the possibility of the occurrence of biliary dyskinesia should be borne in mind and requires consideration in the etiologic analysis, diagnosis and therapy of biliary tract diseases.

PROLIFERATIVE AND EXUDATIVE TUBERCULOSIS WITH REFERENCE TO THEIR RELATIONSHIP TO THE VARIOUS FRACTIONS DERIVED FROM THE TUBERCLE BACILLUS '

By F M POTTENGER, M D , F A C P , *Monrovia, California*

OUR conception of tuberculosis has been subject to vast changes since Villemin proved the transmissibility of the disease and Koch revealed the cause of infection

The pathology of tuberculosis received a clarifying and purifying touch when the discovery of the bacillus showed the unity of all tuberculous processes, and again, when Koch showed that sensitization of tissue cells plays a part in every infection. When the meaning of these two important facts was comprehended we were ready to define the pathologic changes which take place at the site of infection as the reaction of the tissues to the presence of the tubercle bacillus and bacillary products, and to view the reaction of the tissues of previously infected individuals, on again coming in contact with bacilli or bacillary substances, as shown in the phenomena attending subsequent invasion and in the tuberculin tests, as being evidence of a specific defensive mechanism.

The primary reaction in first infection is similar to the reaction of tissues to any foreign substance, but this changes and takes on aspects of specific opposition to the invading living organism as soon as sufficient bacillary substance has gained access to the circulation to sensitize the body cells. Thereafter the more simple reaction of first infection assumes a greater complexity because the entire organism has become prepared in a specific way to meet reinfection and to cope with whatever injurious substances are produced as a result of the growth and destruction of invading bacilli.

The anatomic pathology of tuberculosis consists of the changes in the tissues which are produced when infecting bacilli or bacillary products come in contact with body cells sensitized by bacilli and their products. The clinical expression of tuberculosis consists not only of the changes which are caused by the pathologic structure itself but also of reflex and toxic effects which are expressed in various tissues and organs, disturbing their smooth working and causing departures from physiologic action. It is evident that these expressions may be either local or general.

The difference in reaction of different individuals to tuberculous infection has led to certain groupings of cases according to the predominant characteristics noted. If it were possible for us to know the particular

* Read at the Eighteenth Annual Clinical Session of the American College of Physicians, Chicago, April 17, 1934

factors which determine these major differences, we would thereby greatly increase our understanding of the disease

Even Sydenham and Morton, clinicians of the seventeenth century, recognized an arbitrary classification of tuberculosis into "early," "moderately advanced," and "far advanced" This was based largely on symptomatology and on the recognition of the fact that those with few, mild symptoms were curable and those with serious symptoms were seriously ill and for the most part incurable

Later a classification, using the same terms, was proposed by Turban, which with modifications, is still followed in many countries of the world This classification at first depended on anatomical extent only, but later was modified in the United States by Rathbun's suggestion of adding to it the severity of symptoms, and later by Brown and Heise's suggestion of adding the knowledge gained by the roentgen-ray

These classifications have rendered a great service to tuberculosis, mainly by requiring physicians to appreciate that the smaller the lesion, other things being equal, the more curable the patient, and further by stimulating physicians to develop skill in determining early lesions They have, however, added little to our clinicopathologic conception of the disease

A real understanding of tuberculosis and the ability to predict what course a given infection will take depends upon facts which are more fundamental, facts of an immunologic nature which, if they were known to us, would be sufficient to explain many of the mysteries which at the present time surround the disease

The reaction between the tissues and the bacillus throughout the course of tuberculosis is a combination of cell proliferation and exudation with or without tissue destruction The predominating reaction in different lesions has been used as a basis for classifying them into proliferative or fibroid, exudative and caseopneumonic Miliary tuberculosis is usually classified separately, although it may be predominantly proliferative in one case and predominantly exudative in another

While these reactions are not distinctive and separate, but go hand in hand in the same lesion, yet one or the other predominates sufficiently often to show that a different combination of forces is responsible for the different reactions Anything that will enable us to explain these differences will clarify our knowledge and help us to understand better the specific protective mechanism which the body brings into play when it combats tuberculous infection We must bear in mind that these reactions are a part of the patient's defensive immunity mechanism, or at least are determined by it

What reaction will take place in the tissues in the presence of invading organisms is determined primarily by the tissues themselves and secondarily by the numbers and virulence of the invading organisms That heredity is a factor of great importance is conceded, and that the reaction of the tissues is greatly modified by environment, both internal and external, is likewise recognized On the part of the bacillus, we have two important factors—

numbers and virulence These four factors are the most prominent forces so far as we know in determining the nature of a tuberculous infection

If we now turn to the bacillus we find that, under the direction of the National Research Council, Anderson and his coworkers have separated it into several distinct fractions, and that the effects of these various components on the tissues have been studied experimentally by Sabin, Doane, Cunningham, Long, Seibert, and their coworkers, with the result that certain reactions in the tissues may be more or less accurately assigned to definite bacillary substances

These are among the most important studies that have been made in tuberculosis in recent years, because they give us a basis for understanding the individual reactions of the body against the disease

The following fundamental reactions have now been assigned to the different components of the bacillus by these workers The lipid portion of the bacillus is the cause of the formation of the tubercle The phosphatide constituent seems to possess the simple property of stimulating monocytes and young connective tissue cells to the formation of epithelioid cells and giant cells The waxes cause proliferation of fibroblasts, and the acetone soluble fat induces proliferation of all connective tissue cells and the cells of blood vessels, and is responsible for hemorrhage The polysaccharide is toxic for leukocytes and according to White exerts a damaging influence on the adrenals The protein is responsible for fever, causes proliferation of plasma cells, produces sensitization of the body cells and calls out the allergic reaction later

The lipoids seem to have most to do with the building up of a structural defense while the proteins are more intimately connected with the physiologic protection of the body

While our knowledge is not sufficiently advanced to enable us to discuss the various pathologic changes in their exact relationship to this experimental work, yet we undoubtedly can make certain comparisons which are helpful

Since the two outstanding tissue reactions in tuberculosis are the proliferation of cells, on the one hand, and the exudative reaction of allergy on the other, and since the former has been more or less definitely assigned to the lipoids and the latter to the protein fractions of the bacillus, it might be well for us as clinicians to accustom ourselves to think in terms of these reactions It would seem fair to assume that the lipoids protect the body by holding the bacilli fixed in the tissues, and there is also a possibility that these cells afford a certain protection to the bacilli which they imprison The proteins interfere with the migration of bacilli by causing inflammation and exudation in the tissues which surround them, and if the numbers and virulence of the bacilli are great the reaction may be sufficient to destroy the tissue and eliminate the bacilli en masse The reaction to the protein elements further opposes multiplication of bacilli by increasing phagocytosis

and stimulating other defensive mechanisms of the body which encompass their destruction more rapidly and more efficiently

Now if we examine into the nature of preponderantly proliferative tuberculosis, we note first that it is comparatively mild, and its chief characteristic is new tissue formation. It may extend until wide areas of fibrous tissue are formed before it makes its presence felt by symptoms. It is usually brought to the patient's attention by metastases taking place in some other portion of the lung or in some other organ, or by the process taking upon itself exudative and not infrequently destructive characteristics.

The primary mildness is indicative of a relative absence of physiologic disturbance of the patient, and suggests an infection produced by few bacilli with relatively low virulence which fails to stimulate adequate specific defense. The infection fails to furnish sufficient bacillary protein or to pour toxins into the circulation in sufficient quantities to produce symptoms, and yet regardless of this mildness the tissues are unable to prevent the bacilli from spreading. We must assume, therefore, that there are other factors which require explanation. It would seem that some protection must be present to shield the bacilli from destruction, for they continue to spread regardless of their low numbers and low virulence, or it may be that some factor necessary to encompass their destruction is wanting.

In this connection it will be remembered that Sabin has suggested that the monocytes which are precursors of the epithelioid cells exert a protective influence on bacilli. So the bacilli may not be destroyed, even though they are few in number and low in virulence, consequently they may fail to set free in sufficient quantities the tuberculo-protein which is necessary to build up the patient's physiologic protective mechanism (immunity) to the point of efficiency, although they do set it free in sufficient quantity to sensitize the body cells.

Sooner or later, however, this structural protection, if we may so speak of it, fails, bacilli develop in larger numbers, and through their growth and destruction larger quantities of bacillary protein are liberated which now call forth allergic phenomena and cause the widespread, mild, proliferative lesion to take on exudative characteristics with or without destruction of tissue. When this occurs the allergic reaction may be coextensive with the unhealed lesion which is not infrequently coextensive with the proliferative process, but as a rule, for some time the exudative phenomena are less marked than those found in primarily preponderantly exudative lesions. This indicates that regardless of the minimal amount of bacillary protein which had escaped from the proliferative lesion, sufficient had gained access to the body cells to cause at first sensitization and later a certain amount of desensitization. The chief allergic reaction and the principal destructive phenomena are usually confined to limited areas, it may be a single area at first which may proceed to cavitation. Later, however, when the allergic process becomes more extensive and more severe, multiple small cavities often appear in the midst of the proliferative process.

The supervention of exudative phenomena on a proliferative background probably results whenever the numbers of extensions of the disease become so many at any one time, or whenever they are caused by so large a number of bacilli that local destruction of tissue results and the total amount of bacillary protein set free into the tissues becomes sufficiently great to produce a widespread allergic reaction with or without increased tissue destruction. It would seem then that our best conception of preponderantly proliferative tuberculosis is that it is primarily more a reaction of the tissues to bacilli as foreign bodies than to them as living, multiplying microorganisms which stimulate the body functions to their own destruction, consequently an infection in which structural defense predominates over physiologic defense. Whether this is for the most part due to the cellular protection afforded to the bacilli by the newly formed tissue or to the fact of a failure to set free sufficient amounts of immunizing protein and whatever other substances are necessary to create an efficient immunity is not clear. That bacillary protein may be lacking in these lesions is suggested by the fact that if the course is progressive, the effects of large quantities of bacilli and bacillary protein sooner or later become evident, and the lesion takes on exudative characteristics similar to those of the preponderantly exudative type, and further by the fact that the proliferative lesion may be stimulated to allergic response and healing by bacillary protein as found in tuberculin.

While preponderantly proliferative tuberculosis is mild in degree and usually consistent with long life, it does not heal readily. It is much more difficult to secure a satisfactory recovery from it than it is from the more acute exudative lesions.

Preponderantly exudative tuberculosis, on the other hand, is more acute. Even the early implantations are often made by large numbers of bacilli and are accompanied by the liberation of large quantities of bacillary substances of which the protein fractions are particularly in evidence. Not infrequently the first intimation of illness is accompanied by acute symptoms of toxemia, rise of temperature, weakness, even prostration, and often cough and expectoration. Examination at this time may reveal a widespread exudation in the tissues, not infrequently with loss of tissue. Here, physiologic reaction predominates over structural defense.

The disease may develop slowly as a result of a succession of small implantations of bacilli, or it may come on acutely as a result of massive dosage. In this connection it must be borne in mind that the term "numbers of bacilli" is not a measured dosage but a relative term depending on the individual and his antecedent dosage, for desensitization takes place as a result of repeated inoculations. So what would be a large dose at the beginning of a disease would probably be small later in its course.

With this form of the disease the patient is more severely ill than with the preponderantly proliferative form. There is more danger of the disease spreading quickly and more danger of tissue destruction. On the other hand, a higher immunity develops. The acuteness of the symptoms is

probably caused largely by the protein fractions of the bacillus which produce a widespread exudation with or without tissue destruction, although destroyed tissue products and other bacillary elements can not be excluded. The same dose of bacilli or bacillary protein which causes the acute symptoms seems to whip up the immunizing mechanism and to desensitize the patient so that he is thereafter enabled to withstand the effects of larger numbers of bacilli and of greater quantities of bacillary protein without reacting so severely. While proliferation goes hand in hand with exudation and destruction, yet it is relatively a minor part of the early stage of preponderantly exudative lesions but a very important part of the healing process.

Preponderantly exudative lesions yield readily to treatment if it is applied at once. The infection is not coextensive with the exudative phenomena, but must be looked upon as being a limited infection with a large local tuberculin reaction which, when it has cleared away, which it will do largely by resolution, will leave a fairly free lung field. Being acute it comes on before the lung has been seriously injured and when its power to make necessary compensation for healing is unimpaired.

FURTHER STUDIES ON GRANULOPENIA WITH A REPORT OF TWELVE CASES¹

By STEWART R. ROBERTS, F A C P, and ROY R. KRACKE,
Atlanta, Georgia

SYNONYMS

WITH the increasing incidence of this disease, it is natural that new terms should be used. The original name was agranulocytosis and the indices usually refer to it under this heading or as agranulocytic angina. Agranulocythemia and hypogranulocytosis are also used—the former as a synonym of agranulocytosis and the latter to mean a leukopenia but not a complete granulopenia. Malignant neutropenia and primary granulocytopenia are used in the same sense as agranulocytosis or complete granulopenia. Primary granulopenia is also used in the sense that the granulopenia does not result from any other disease. Two points need to be distinguished. Complete granulopenia or near complete granulopenia or agranulocytosis is a rare and dangerous disease of the bone marrow. Mild or moderate granulopenia is a very common state of the blood stream and not in itself very dangerous. Complete granulopenia is a disease, leukopenia a mild decrease in the leukocytes. If the terms be limited to the granulocytes, one may distinguish the two conditions as complete and incomplete granulopenia. Partial or total granulopenia are other qualifying adjectives meaning the same thing. We prefer the terms complete and incomplete granulopenia to distinguish the rare disease from the frequent state.

THE MECHANISM OF COMPLETE GRANULOPENIA

To understand the mechanism of the disease is to understand the disease itself with, of course, certain limitations in our present knowledge. The order of events in this mechanism was submitted at length in our first paper¹ and we believe with reasonable evidence of proof. There are five stages of the disease and they follow each other with inevitable and inexorable regularity. First and for some reason, now largely speculative, there is the bone marrow onset. The bone marrow is an organ and its myelocytic function fails. So far as we can see, it makes little difference whether one speaks of this selective myelocytic failure with cessation of the production of the granulocytes as a myelocytic aplasia, myeloblastic dysfunction, cessation of maturation, allergy or what not. It is a selective bone marrow failure with a resultant blood stream granulopenia even to the point of a complete absence of the circulating granulocytes. Secondly, about four days after this bone marrow failure, there is the blood stream onset. The

¹Read at the Chicago meeting of the American College of Physicians, April 19 1934

change may appear in the blood count in one to two days with gradual lessening of the granulocytes to complete or near complete absence. Thirdly, the clinical onset comes more quickly, usually in 24 to 48 hours with complete granulopenia, weakness, prostration, and fever, rarely early mania and later exhaustion and delirium. Fourthly, the granulocytes protect the tissues with an ever present daily immunity from bacterial invasion. This protection is now lost, and bacterial invasion begins. Therefore, so far as is now known, this is a non-bacterial disease with a bacterial ending. Blood stream infection, tissue necrosis and gangrene, ulceration and hemorrhage follow. This is the stage of sepsis. Fifthly, and lastly, the parting of the ways has come. It is granulocytes or death. There is no mid course. The bone marrow may even resume its myelocytic function, but death may occur from sepsis before maturation proceeds to the appearance of myelocytes and granulocytes in the blood stream. This is the mechanism of complete granulopenia. One may object that this is too mechanistic a conception for a hematological problem, but the facts square with the conception.

RELATIVE FREQUENCY OF MILD GRANULOPENIA AND THE CHRONIC GRANULOPENIC PATIENT

In our second paper we² studied the general subject of granulopenia and made comments illustrating the granulopenic trend on the basis of blood studies on 8,000 private patients. The general conclusions have been confirmed by a similar study made by Mettier and Olsan³ at the University of California Hospital on 10,000 cases between 1920 and 1931, inclusive. A study of our paper and their paper shows the frequency of leukopenia, its trends and its wide implications. In general it may be said that leukopenia is an important factor and probably as important as a leukocytosis.

The granulopenias are classified under 10 different headings of which acute complete granulopenia is only one. A chronic granulopenia is described of which acute granulopenia is probably an extreme degree. One out of every four patients may be expected to have a mild granulopenia. One of two female patients between the ages of 40 and 60 may be expected to show a mild granulopenia. The complaints of weakness, exhaustion and fatigue are twice as frequent in the granulopenic patients as in those with normal white cell counts. There appears to be a definite even if rather vague clinical syndrome that consists mainly of weakness, easy exhaustion and chronic fatigue, a loss of strength with physical inertia associated with a chronic diminution in the number of granulocytes. The severity of these symptoms which are, of course, largely subjective, seems to depend upon the degree of diminution of the granulocytes until with complete absence of the granulocytes such as characterizes an acute complete granulopenia, there is extreme weakness and physical collapse. Mettier and Olsan found 1,167 patients out of 10,000, or 11.67 per cent, with granulopenia. Their figures show 52.4 per cent in females and 47.6 per cent in males. They classified 9.7 per cent of their cases of leukopenia as "benign leukopenia of obscure

origin" The careful and prolonged study of a single leukopenic patient rather than the mass study of many leukopenic patients promises valuable results

Granulopenia whether acute, chronic or recurrent, is regarded as a disease entity in the same sense and as definitely as pernicious anemia is so regarded Granulopenia, when associated with other diseases (usually then called leukopenia) is not rare, and here Fitz-Hugh and Comroe²⁰ well call it "a mere hematological manifestation" of other diseases Among these may be mentioned typhus and typhoid fever, influenza, measles, mumps, dengue fever, certain stages of tuberculosis and syphilis, fulminant sepsis and later stages of extreme anemias It is a common and widespread hematological condition long known and often used as a diagnostic aid A college student with 80 per cent lymphocytes in a total leukocyte count of 1,600 was treated for the disease acute granulopenia, but developed on the fourth day definite signs of typhus fever, and an old man of 77 with only 34 per cent granulocytes in a total count of 2,000 was proved to have an advanced hypochromic anemia A leukopenia with complete or near complete absence of the granulocytes, which constitutes the essence of the disease granulopenia or agranulocytosis, is one thing, and a leukopenia that is a blood sign of a disease of which it is a part, is quite another thing Fine judgment and acumen may be necessary to make the differentiation Sometimes only waiting will solve the problem The point to be emphasized is that a low granulocyte count is not of itself proof of the disease granulopenia

Granulopenia occurs in aplastic anemia Here all three of the elements in the bone marrow are affected, viz, the granulocytic, the erythrocytic and the thrombocytic cells In the disease granulopenia only the myeloblastic tissues are involved Wide variations and gradation occur in the count of the granulocytes in pernicious, aplastic, and hypochromic anemias, and even in the aleukemic states of the various leukemias and particularly the myeloid type In the last great care is necessary, for a leukemic patient may present a leukocyte count of 2,000 or less The majority of these cells may be the blast type of the myeloid series It is easy on account of their relatively small size to call them lymphocytes in error and make the diagnosis of granulopenia At times a myeloid leukemia is so closely imitated by the leukopenia of other diseases, including certain anemias, that one must take all precautions to be sure of the diagnosis Complete granulopenia seems to characterize agranulocytosis alone It is the case of incomplete granulopenia that brings the greater difficulty Of course the clinical signs and symptoms are of great aid

THE WORLD INCIDENCE AND GEOGRAPHIC DISTRIBUTION OF COMPLETE GRANULOPENIA

Our present knowledge of the world distribution of granulopenia is dependent upon reports in the literature The diagnosis of the disease depends upon the study of the blood, and in those areas and countries where

blood studies are the exception rather than the rule, the disease may occur as frequently as in America or Germany and yet be overlooked. Even in America it is reported far more frequently as a rule in those centers where a certain group are particularly interested in the disease, its problems and treatment. Blood studies are requisite for its recognition. There seems no available reason why it should not appear as frequently in England as in other civilized countries and the failure to make systematic blood counts is probably the reason for the paucity of English reports. From the literature to date (and more cases are reported from month to month) there is evidence that it is of world-wide distribution. The facilities for blood studies and for reporting disease are probably more highly developed in Germany and the United States than in other countries, and these two countries so far furnish the majority of reported cases. We have summarized 473 cases in the United States and over 400 in Germany. Reports continue to come in from France and Italy. It has been reported from Japan, China, Dutch East Indies, Russia, Poland, and Syria. Dennis⁴ writes that cases have been seen in Palestine and Egypt, and several cases have been studied by Dr Kleeborg in Jerusalem. So far only six cases are reported from England. Time will finally show its real incidence and distribution.

AGE, RACE, SEX, OCCUPATION AND SOCIAL INCIDENCE

Acute granulopenia may occur at any age from less than a year to more than 80 years of age. The majority of cases occur between 30 and 50 and the average age of the 473 cases reported in the United States is between 40 and 50 years. It is chiefly a disease of middle life so far as reported cases show. This age incidence is an urge to complete and even repeated blood studies in cases of doubtful diagnosis.

So far the disease affects principally the white race. Its frequency in the yellow races is unknown. Further reports are necessary to clear this point. We have not observed a single case in the negro over a period of five years and with an annual admission rate of 75,000 negroes to the Emory University Division of the Atlanta City Hospital. This rarity in negroes seems to be true throughout the continental United States. Further facts are necessary before its final incidence in negroes can be stated. Sick negroes outside hospitals rarely have blood counts and most sick negroes never enter a hospital. In the eight cases listed below in negroes, the clinical onset in nearly all of them followed the administration of arsphenamine. The following table gives the present trend of race and sex incidence.

TABLE I

| | |
|-------------------------------------|-----|
| Number of cases in the U. S. | 473 |
| Number of cases in the white race | 442 |
| Number of cases in the colored race | 8 |
| Race not stated | 23 |
| Number of cases in males | 161 |
| Number of cases in females | 310 |
| Sex not stated | 2 |

Thus far the disease is reported in the ratio of nearly two females to one male, or actually of 310 females and 161 males. This ratio is very difficult to interpret and particularly in regard to etiology. Probably one-third to one-half of the very sick people in this country do not have the interpretative benefit of a blood count and further studies may change this ratio. Of our 12 cases, eight were women and four, strong men.

A case in point was that of a school teacher that one of us (S. R. R.) was called in to see in 1927. She had already previously been seen by two physicians, but although the patient was very ill and had become unconscious, no blood examination had been made. Had she been a nurse, she would doubtless have been taken to the hospital at the beginning of her illness and the diagnosis been made promptly. As it was, the disease was overlooked, and the diagnosis made of streptococcic throat was in error. A majority of people who die in the world never have had the benefit of a blood examination. We do not know how many people have complete granulopenia and must resist the temptation to leap to a speedy conclusion from a very limited experience over a very short period of time.

SOCIAL INCIDENCE

It is apparent thus far that a majority of cases reported appear among those in the middle and upper classes, in the higher economic and cultural levels. On the other hand, the great majority of people on the lower economic levels postpone treatment, or may not see a physician until necrosis of the throat is so far advanced as to permit a glib diagnosis of malignant sore throat, or have no hospital facilities and no opportunity to receive a correct diagnosis. More facts are necessary for a conclusion involving social incidence. In American medicine one does well to remember that there are 125 million people in the United States and that many millions of them do not have the benefit of any modern medical facilities, much less adequate medical care.

OCCUPATION

The following table shows the occupation of 250 of the 473 cases in the United States. In 223 cases data as to occupation are not furnished. Conclusions, or even intimations, from such a table are scarcely warranted. However, it is apparent that to date the disease has appeared most frequently in housewives and in persons falling into the medical group.

TABLE II

| | |
|--------------------------------|--------|
| Housewives | 102 |
| Physicians | 22 |
| Nurses | 17 |
| Hospital employees | 4 |
| Medical students | 3 |
| Laboratory technicians | 1 |
| Relatives of physicians | 11 |
| School teachers | 2 |
| Farmers | 5 |
| Business men—all types | 10 |
| Sixty other occupations (each) | 1 or 2 |

Many have noted this predilection of the disease for physicians and their families, nurses, medical students, technicians and others of the medical group. It has been commented upon in the papers of Kracke^{17, 21} and by Stellhorn and Amolsch.⁷ Among Harkins'⁵ eight cases there were a doctor, a medical student and a nurse. In Madison and Squier's⁶ series of 14 cases there were five in the medical group counting the wives of two physicians, and the authors write, "In this group (of cases) as in the disease at large, there seems to be a remarkable relation to the medical and allied professions." This statement undoubtedly applies to the group of cases they reported but probably does not apply, in the same proportion, to "the disease at large." In our group of 12 cases, for example, there were only two, a physician and a nurse, from the medical group. It is true that of the males reported 13.6 per cent are physicians and of the females 5.4 per cent are nurses. A factor of some importance in determining this rather large percentage of the medical group is that sick doctors and nurses go more quickly to hospital in our experience than do others and more quickly receive the benefit of repeated laboratory examinations and consultations. In the medical group so rare a disease or so baffling a case would probably receive the most thorough study and the quickest diagnosis.

Comment is certainly justified upon the fact that the disease has occurred most frequently in women and especially among those classified as housewives, of the eight women in our series seven were in this occupation, if it may be so called. To date the data from reported cases allow of no difference of opinion on these points.

PRESENT IDEAS OF ETIOLOGY

The cause of the disease is unknown. From the present evidence, there seems to be no single etiological factor that fits every case, nor has it been proved that any of the possible causes that have been suggested are responsible for the disease. With a new disease one fishes quickly in the pond of cause and effect in the hope that the prize fish of etiology may soon swallow bait, hook and sinker. All these excursions ultimately will result in the discovery and proof of the etiology. One steps very carefully here. Coincidence does not necessarily mean proof. Different points of view, clinical observations and experiments with animals all produce positive or negative evidence, and all are valuable. The various suggestions as to etiology offered by students of the disease are summarized in the following table.

TABLE III

- 1 Specific bacterial etiology nothing conclusive discovered
- 2 Abnormal menstrual states
- 3 Certain anemias, aplastic, pernicious and secondary
- 4 After leukopenic diseases, as influenza
- 5 Certain drugs, as arsphenamine, amidopyrine and benzene ring compounds
- 6 Exhaustive states, induced by toil, worry, and mental effort
- 7 Certain senile states in asthenic women

1 *Bacteria* Since Lovett⁸ reported the first case of this disease in the United States many studies have been made in an effort to incriminate a specific bacterium. She attempted to show that the *Bacillus pyocyaneus*, which she found in the oral ulcers of her patient, was responsible, but without success. Since that time much experimental work has been done with bacteria in an effort to reproduce the disease in laboratory animals but it has been uniformly unsuccessful. Many of the bacteria involved have been the various streptococci, the *Bacillus pyocyaneus*, bacillus of hog cholera, dead and living typhoid bacilli, Vincent's organisms, etc. Many writers have stated that various degrees of granulopenia have been produced in laboratory animals with these organisms but apparently they did not take into account the fact that transient and temporarily severe leukopenic states can be produced with nearly any and all bacteria, dead or living. A significant contribution is that of Dennis,⁹ who was able to produce a prolonged granulopenia by the introduction of *Streptococcus viridans* in parchment capsules into the peritoneal cavity of rabbits. One of us (R. R. K.) has repeated, in so far as possible, this work and is unable to confirm the results of Dennis.

There seems no evidence that there is a specific bacterial etiology. Positive blood cultures were obtained in about 20 per cent of the total number of cases, they were positive in 70 per cent of the cases on whom cultures were taken. The streptococci were by far the most frequent invaders. There were 74 positive cultures and 395 cases in which cultures were either negative, or not stated as taken. The data in table 4 illustrate this point in detail.

There is no more reason to suspect a bacterium to be the cause of this disease than to suspect a specific bacterium to be the cause of aplastic anemia. On the other hand, as we¹ have shown in our first paper, the blood stream infection is probably secondary to the leukopenic state. One must keep the horse of acute granulopenia with the loss of immunity to bacterial invasion ahead of the cart of the secondary bacterial invasion. This explains why so many different bacteria are recovered in blood cultures. This explains why the usual surgical treatment of the secondary infection and necrosis is so unavailing. This explains in terms of treatment why this secondary infection, particularly with pus producing bacteria, is the chief therapeutic hope of the patient, because it is nature's method of quickly arousing a leukocytosis.

2 Hubble¹⁰ suggests that glandular dysfunction may play a rôle in producing the disease and suggests that bone marrow depression may be caused by a pituitary basophilic insufficiency or granulopenia by cortical adrenal dysfunction. Corey and Britton¹¹ observed an agranulopenic syndrome in adrenalectomized cats and Thompson¹² believes that the disorder may be associated in some way with the glandular changes of menstruation. Thompson's studies are worthy of serious consideration. Our case 8 was afflicted with menorrhagia as well as great toil and worry. The temptation may be to dismiss these suggestions as too speculative.

TABLE IV
Blood Stream Infection in Granulopenia

| Organism | Number of Cases |
|--|-----------------|
| <i>Streptococcus hemolyticus</i> | 8 |
| <i>Streptococcus viridans</i> | 15 |
| <i>Streptococcus</i> (type undetermined) | 9 |
| <i>Staphylococcus albus</i> | 3 |
| <i>Staphylococcus aureus</i> | 4 |
| <i>Bacillus Friedlander</i> | 4 |
| <i>Pneumococcus</i> , type 2 | 3 |
| <i>Pneumococcus</i> , type 3 | 1 |
| <i>Pneumococcus</i> , type 4 | 2 |
| <i>Pneumococcus</i> , type undetermined | 2 |
| <i>Diplococcus</i> (undetermined) | 4 |
| <i>Bacillus pyocyaneus</i> | 3 |
| <i>Bacillus paratyphosus B</i> | 1 |
| <i>Bacillus coli</i> | 3 |
| <i>Bacillus proteus</i> | 1 |
| <i>Streptothrix</i> | 3 |
| <i>Streptococcus</i> with other bacteria | 9 |
| Fusiform bacillus (Gram negative) | 1 |
| Estivo-autumnal parasite | 1 |
| Various cocci | 3 |
| <i>Staphylococcus</i> (undetermined) | 1 |
| <i>Diphtheria bacillus</i> | 1 |
| Vincent's organisms | 1 |
| Typhoid bacillus | 1 |
| <i>Bacillus</i> (undetermined) | 1 |
| Total number of positive cultures | 74 |
| Negative, or not stated | 395 |

3 The possible relation to certain blood diseases is discussed under the heading of "Relation to Other Diseases." Suffice it to say here that other anemias may depress the myelocytic function of the marrow with a resulting granulopenia. Such a granulopenia may thus invite bacterial invasion and hasten death. We have seen this in a case of acute lymphatic leukemia. It is common in aplastic anemia to see a granulopenia.

4 Cases 2, 5 and 7 of our series followed influenza in an influenza epidemic. We have before pointed out the great weakness and prostration in the acute infections characterized by granulopenia.

5 There has been much recent discussion following the suggestion that arsphenamine, amidopyrine and benzene ring compounds may cause the disease. Much of the discussion about the relative frequency of the disease in the medical group of occupations, i.e., doctors, nurses, technicians, etc., finds its point here. The granulopenic state following arsphenamine administration in certain cases has long been recognized. The frequency of granulopenia in those treated with gold salts for tuberculosis has been observed by several French writers^{13, 14, 15}. The possible rôle of certain coal tar drugs in the production of the disease has been stressed by Kracke^{16, 17}. Madison and Squier⁶ have presented evidence that all of their cases were given drugs of this class preceding the clinical onset. Chief among these drugs under suspicion at this time is amidopyrine alone or in combination

with a barbiturate. On the other hand, Thompson¹⁸ states that he has carefully investigated the histories of his 46 cases of granulopenia and that there is no evidence to incriminate either amidopyrine or the barbiturates. Circumstantial evidence continues to accumulate that amidopyrine in certain cases has power to depress the myelocytic function of the bone marrow.²³ This is certainly not true, however, of all persons to whom amidopyrine is administered. These differences in myelocytic response to amidopyrine intimate therefore that the myelocytic function of the bone marrow varies in the degree of its sensitivity. Pepper¹⁹ refers to the allergic predisposition of individuals who have granulopenia. We have not confirmed his suggestion in our series. Perhaps one who has granulopenia may have a weakened or inferior marrow which may be hypersensitive to allergic influences, but this would be very difficult of proof.

EXHAUSTIVE STATES

It is curious that cases 1, 2, 3, 4, 6, and 10 of our 12 cases, and another case reserved for a later report, and not included in this series, were lean, pale, asthenic women of little reserve. Each of them lived on a lower level of strength and activity than normal and one could well call them frail, exhausted women. Their families spoke of them as "lacking strength, complaining of weakness and unable to stand much strain." Most of them were of middle age or older and physically below par with a hemoglobin ranging from 60 to 70 before granulopenia developed. One can only speculate here that the bone marrow, viewed as an organ, may become selectively exhausted or disturbed to such a degree that normal function is impossible. There is selective failure of the myelocytic function of the bone marrow. We have seen erythrocytic failure repeatedly in senile hypochromic anemia. Cases 8 and 11 of our series had their attacks after prolonged toil, loss of sleep and great worry and each of them had been warned long before the attack that she could not continue to work so hard. Women of a certain asthenic type and women of great toil form a suggestive group.

THE HEMORRHAGIC TREND IN COMPLETE GRANULOPENIA

In the reports of the postmortem examinations one finds recurring references to hemorrhages both dermal and visceral. A study of this hemorrhagic tendency affords material for a good paper. We have seen during the course of the disease petechiae on the conjunctiva, the oral and rectal mucosa, the skin, then larger purpuric areas even to a massive purpuric area involving one-third the trunk. Bleeding may occur from the nose, throat, alimentary tract, urinary tract, uterus and vagina. Such bleeding is as a rule small in amount. We have seen at postmortem examination petechial and larger hemorrhages in the lungs, subpleural hemorrhages, and petechiae in the epicardium, endocardium, stomach and intestines.²² In one case

there was an acute hemorrhagic splenitis. Sepsis may be an important factor in the production of these hemorrhages. The platelets may show a marked decrease. No hemorrhages may be seen during life and yet necropsy may reveal many. It is rare to see a case in which there is not some manifestation of this hemorrhagic trend. With large purpuric areas the superficial likeness to purpura may confuse the diagnosis and we have seen this mistake made once. This tendency to hemorrhage probably arises from a bone marrow dysfunction involving the megakaryocytes and a decrease in platelet formation. Complete granulopenia may masquerade with a purpuric front. Careful blood studies tell the story. Purpura hemorrhagica may be cured with transfusion or splenectomy, but not a complete granulopenia.

REPORT OF TWELVE CASES

The following 12 cases, only one of which has been previously reported, illustrate definite points in the disease. We have another case for a future report because there have been two attacks and we have followed the blood carefully over a period of two years.

The more one studies these cases and the hemograms, the more the evidence points to the reappearance of granulocytes in the blood stream as the one chief purpose of treatment and the one hope of recovery. Table 5 gives a condensed summary of these 12 cases, and the history of each case more in detail follows.

CASE REPORTS

Case 1 Mrs W W F, aged 46, a patient of Dr W F Shallenberger, had five cystoscopic examinations during 1928. Otherwise she appeared well. Four days after the last examination on November 16, 1928, she became extremely weak, an unexplained fever developed and she died on the third day with a leukocyte count of 400 cells.

Case 2 Mrs L Z R, aged 72, an asthenic woman with a chronic secondary anemia, developed on March 12, 1929 fever, prostration, a red, edematous and quickly necrotic throat, and a white cell count of 2,000 with no granulocytes. She was unconscious and delirious, with a profuse diarrhea. Concurrent with the development of embolic abscesses in the skin and deep abscesses in the muscle of the calf, she showed a widespread infection with the *Streptococcus hemolyticus* in the blood stream, skin and muscle abscesses. Despite the previous absence of granulocytes for days, myelocytes and juvenile forms began to appear in the blood stream after the abscesses developed, and in eight days she had a leukocyte count of 41,000 with 84 per cent granulocytes. She had been convalescent for 65 days and appeared to be in better health than formerly, when the white cell count quickly dropped to 400 with complete absence of granulocytes and she died on the fourth day of the second attack.

This case has previously been reported in detail, and affords proof that the bone marrow in severe acute complete granulopenia may not be irreparably damaged, but with time and stimulation of myelocytic activity may still be capable of normal function. We believe that the stimulation in this

TABLE V

| Case | Sex | Race | Age | Occupation | W B C | R B C | Platelets | Hemor- rhage | Bone Marrow Regeneration* | Terminal Infection | Result |
|------|-----|------|-----|--------------|-------|-----------|-----------|-----------------|------------------------------|-----------------------|-----------------|
| 1 | F | W | 46 | H W | 400 | | | None | Died 1st attack | None | Died |
| 2** | F | W | 72 | Ret H W | 400 | 3,500,000 | Normal | None | Yes | Strep hemo | Died 2nd attack |
| 3 | F | W | 34 | H W | 450 | 4,000,000 | Normal | None | No | No | Died |
| 4** | F | W | 44 | H W | 470 | 5,200,000 | Normal | None | Yes | No | Died 3rd attack |
| 5 | M | W | 50 | Physician | 400 | 3,160,000 | Normal | None | No | Broncho- pneumonia | Died |
| 6 | F | W | 35 | H W | 400 | 2,800,000 | Decreased | Yes | No | No | Died |
| 7 | M | W | 64 | Police chief | 950 | 3,700,000 | Normal | No | No | No | Died |

* Bone marrow regeneration refers to development of leukocytosis after granulopenic attack

** Case previously reported in detail

case was due to the infection with *Streptococcus hemolyticus*. This case also proves that the fall and absence of the granulocytes precedes by one or more days the clinical onset of the disease.

Case 3 Mrs R G, aged 34, had influenza in early March of 1931. She had been weak and unable to resume her usual activity. She had run a slight post-influenzal temperature and on April 7 was confined to her bed on account of weakness and fever. The leukocyte count was only 2,000 and granulocytes were absent. The course of the disease was septic and stormy and death occurred on the seventh day with a total white count of 450, all lymphocytes. Postmortem examination showed a hypoplastic bone marrow, patched yellow and red, with numerous subpleural and subperitoneal petechial hemorrhages.

This case illustrates severe acute complete granulopenia, a normal platelet count, no clinical evidence of hemorrhage and yet multiple small hemorrhages at necropsy.

Case 4 Mrs F P S was an asthenic woman who had long suffered with methemoglobinemia and its characteristic slate blue color. For some weeks she had complained of weakness and fever and had presented evidence of mild sepsis. Her leukocyte count was 900 with no granulocytes. The count gradually fell to 470 and rose during the next 25 days to 5100 leukocytes with 80 per cent granulocytes. This attack began on May 13, 1930. On June 30, 1930, 48 days later, she developed a pleurisy with effusion, with a leukocyte count of only 2500. On July 16 her leukocyte count had risen to 4000. A third attack of granulopenia occurred on November 22, 1930 with a total leukocyte count of only 200, entire absence of granulocytes, and death the next day, November 23, 1930.

This case illustrates again that the bone marrow is capable of regeneration within limits. The woman recovered from two attacks only to die in the third. It also shows the association of methemoglobinemia with complete granulopenia. She gave a history of having taken phenacetin for the three previous years and this was probably the cause of the methemoglobinemia.

Case 5 Dr C E S, physician, 50 years of age, was taken acutely ill on April 9, 1931, with a leukocyte count of 1450, and no granulocytes. He had done a heavy practice for the preceding six months by day and night and in the middle of March had suffered a rather severe attack of influenza. He ran a stormy septic course in his final illness with a gradual fall in the granulocytes and died on the fifth day of a terminal bronchopneumonia with a total white count of only 400. There was necrosis and edema of the throat. Purpuric areas developed over the elbows. During a transfusion, blood was seen to pass outward through the wall of the median basilic vein and infiltrate the surrounding tissues. Purpuric areas appeared at once on the adjacent skin. The blood pressure was 125 systolic and 100 diastolic. His liver and spleen both were palpable. Hiccoughs were frequent. Profuse diarrhea and emesis occurred, and moderate delirium alternating with periods of orientation were noted. Necropsy was refused.

This case illustrates the damage done to at least one vein. He probably had many hemorrhages throughout the body. It is noteworthy that the case followed influenza, and the influenza followed a period of great exhaustion.

Case 6 Mrs M N, aged 35, fell ill on April 18, 1931 with a necrosis of the throat following acute follicular tonsillitis which had lasted for 18 days. For the 10 days previous to April 18 and the onset of the necrosis, her temperature had averaged 103°. She was prostrated with weakness. Her leukocyte count was 2100 with 2 per cent granulocytes. There was a stormy course with sepsis and hemorrhages and she died on the eighth day with a total white count of 400 and no granulocytes. The necropsy showed many hemorrhages in the skin, subcutaneous tissues and viscera.

This case illustrates the hemorrhagic trend associated with complete granulopenia and its secondary sepsis. The platelets were only slightly decreased. Sepsis followed the granulopenia. The bone marrow did not respond to the stimulation of the sepsis.

Case 7 Mr M D G, aged 64, chief of police, had been in excellent health for the past year. One week before his acute attack of granulopenia he had influenza. On March 7, 1930 he had fever and was weak and felt badly. On March 8, he had a chill and his throat was red. On March 9, he had a total leukocyte count of 2260 with no granulocytes. He died 48 hours later with a count of 950. There was no evidence of necrosis.

This case illustrates that an acute complete granulopenia may come like a storm, run a rapid course and cause death in four days with no evidence of necrosis. He had no visible evidence of infection at any time save the redness of the throat. There was hardly time for sepsis to develop. The cause of death was evidently the mere absence of the granulocytes.

Case 8 Miss M L, librarian, 48 years of age. For the past three months she had nursed both of her aged parents, done all the house work including the cooking and washing, worried much, was in the menopause and had suffered two moderate uterine hemorrhages. On August 12, 1934, she began to feel ill and noticed that her throat was red and slightly sore. She became weaker, with increasing redness of the throat and more and more prostration, and on August 15, 1932, a hemogram showed a total leukocyte count of only 950, with no granulocytes. She showed the characteristic physical prostration, and mental dullness varying from delirium to coma. She died on August 20 with a leukocyte count of 450, not a granulocyte was seen during the entire course of her illness. A *Streptococcus hemolyticus* was isolated from the blood stream. Necrosis and edema of the throat were extreme. Necropsy results were unimportant except that a gas bacillus was cultured from the necropsy blood.

This case illustrates acute complete granulopenia following a long period of exhaustion, and associated with two previous moderate uterine hemorrhages.

Case 9 Mr F S, mill worker, 50 years of age, was admitted to the hospital on February 23, 1931, complaining of pain in the lower left quadrant of the abdomen of two months' duration. His blood count showed 8500 leukocytes with 60 per cent granulocytes. A diarrhea was present, and examination revealed multiple superficial ulcers in the sigmoid and rectum. His liver and spleen were palpable. On April 2 his leukocyte count had fallen to 1500 with only 2 per cent granulocytes. Sepsis developed with necrosis in the mouth and throat. A sternal puncture was done and the examination of the bone marrow revealed marked hyperplasia and not aplasia. Four days later the total leukocyte count had quickly risen to 22,000 with 70 per cent

granulocytes. The patient was, of course, much improved. The leukocyte count continued normal or above until May 29, when it quickly fell to 600 leukocytes with no granulocytes and the patient died the next day. During the first attack there was also necrosis at the anal margin.

This case illustrates two attacks of granulopenia. The patient recovered from the first attack because the myelocytic function of the bone marrow was resumed. His sternal puncture and bone marrow study were made during the first attack, but at a time when the marrow had resumed its activity and become hyperplastic. This is proved by the fact that myeloblasts, promyelocytes and myelocytes were found in the bone marrow smear at a time when the peripheral cell count was only 450 with no granulocytes. The condition of the bone marrow resulted four days later in a total leukocyte count of 22,000. At necropsy following death in the second attack, the bone marrow was markedly aplastic. The patient had died because the bone marrow in the second attack did not resume its myelocytic function, and granulocytes did not appear in the blood stream.

Case 10 Mrs. A. L. K., aged 38, a patient of Dr. Trimble Johnson, whom we saw in consultation, entered the Emory University Hospital on March 30, 1933, complaining of fatigue and sore throat of several years' duration. She was an asthenic woman with a reddened throat and small pharyngeal ulcers. The total leukocyte count was 950, and no granulocytes were seen. The leukocyte count remained at this level for three days, during which she ran a septic temperature and quickly developed a deep necrosis of the left foot and the lower one-third of the leg. In five days the leukocyte count had risen to 30,250 with a predominance of granulocytes and myelocytes. During the next 30 days the leukocyte count gradually fell to normal and the foot and leg gradually healed. There was much sloughing of the necrotic area. She is still well, one year after recovery from the first attack.

It seems to us that the chief factor in her treatment was the development of the extensive necrosis and gangrene of the left foot with its coincident stimulation of the bone marrow. The organisms isolated from the necrotic area were all pyogenic in type. This necrosis and these pyogenic bacteria confirm our conception that infection is secondary to the granulopenia and that the patient's chief chance of recovery is afforded through the secondary infection itself.

Case 11 Miss S. K., white female, aged 26, a nurse, patient of Dr. C. W. Strickler and Dr. Lon W. Grove, whom we saw in consultation, had been working very hard for the past several months. She was admitted to the Emory University Hospital September 9, 1933, complaining of weakness, general aching, fever and chill occurring the previous day. Physical examination was negative except that she had had a superficial skin eruption of the fingers of the right hand. The total leukocyte count was 2,000 with 4 per cent granulocytes. She grew rapidly worse, sepsis developing with high fever, and necrosis and edema of the right hand. Death occurred on the seventh day with a total leukocyte count of 300, with no granulocytes. The blood cultures were negative.

This is the second case we have seen which had a chill. There had been a mild vesicular eruption of the right hand with superficial ulceration, the

necrosis took hold here rapidly and deeply, and the edema extended quickly as high as the right axilla. Even with such inflammation and necrosis the bone marrow did not respond to its stimulation.

Case 12 Mr J P M, aged 42, executive, patient of Dr J P Tye of Albany, Ga, entered the hospital on January 16, 1934 with marked weakness, physical prostration and a red and edematous throat. One year previously his physician had told him that he had a low white cell count. During the past year he had suffered with multiple arthritis. For eight days he ran a stormy septic course, with increasing fever and progressive weakness. The total leukocyte count dropped to 400 with no granulocytes. Death occurred on the eighth day.

Here was an instance of the disease attacking a strong, though slightly obese, individual, a man of great muscular development, a former football star, who had lived a vigorous outdoor life up to his last illness, with the exception of the limitations imposed by the moderate multiple arthritis. Two of our cases were of this type and both died. Here was acute complete granulopenia that ran a stormy course with complete myelocytic failure.

THE CAUSE OF DEATH

Nature has certain requirements for the existence of the individual. Oxygen, for example, is necessary for life. There is so little reserve of oxygen in the tissues and the need for it is so urgent and imperative, that one can hold one's breath only for about a minute or less. Similarly, the granulocytes seem necessary for the existence of the individual. Complete granulopenia seems to be the first disease that has almost dramatically forced this fact to our attention. One may live with 2,000 or 200,000 granulocytes but without them there can be no life. As a rule, in proportion as the granulocytes fall below the normal level, so does robust living lessen. Nature appears to have given the granulocytes a wider amplitude of daily variation than any other cell of the blood. The count may dip and rise under many influences. Normally they vary with the daily ebb and flow, but in time of need they rise with exercise, inflammation, excitement and even food. The granulocyte may be regarded as a highly specialized cell with multiple functions. These cells and these functions are necessary for life.

1 One function seems to be to confer upon the tissues of the normal individual an ever present daily immunity to bacterial invasion. In complete granulopenia this immunity is lost, and one to four days after the granulocytes disappear from the blood stream, bacterial invasion usually proceeds rapidly. This invasion is stopped and the living bacteria in the blood stream and tissues cease their activity and die, or are eliminated, only by the reappearance of granulocytes in the blood stream. Without granulocytes there is sepsis, and with sepsis there is death unless the granulocytes reappear.

2 It seems that the presence of the granulocytes is necessary to the individual for the maintenance of his daily normal strength. In complete

granulopenia, even before bacterial invasion has taken place, we have repeatedly seen the quick phases of fatigue, exhaustion, prostration and even collapse. We have seen this progressive loss of strength in our first case and consistently in all the subsequent cases. It is bedside observation with proof. The longer the granulocytes are absent, the greater the prostration. This prostration may be contrasted with the maniacal struggles of the patient with meningitis and with leukocytosis, or the thyroid-like activity of the patient with subacute bacterial endocarditis.

3. Concurrent with this loss of strength, perhaps as a part of the same process, and likewise before bacterial invasion, there is a dulling of the mental functions, a falling away of the normal vividness and awareness of the immediate surroundings, a loss of memory, a sleepy silence, then a muttering delirium or a deep unconsciousness. Memory is gone days before death comes.

4. No one has yet accounted for the rising fever of complete granulopenia that comes before sepsis. It is very difficult to state when sepsis begins and one can note its beginning with only relative accuracy. With immunity gone, one does not know how quickly bacteria invade the intestinal wall and pass to the adjacent tissues. The appearance of multiple ulcers in the intestinal mucosa is probably synchronous with the necrosis of the mouth, throat and rectum. Nevertheless, this curious fever precedes the evidence of sepsis. This fact seems to intimate that one of the functions of the granulocytes may be to aid in heat control.

With the loss of immunity to bacteria, the loss of strength, the prostration of the mental functions, the rising fever, and then a quick sepsis, death is inevitable unless a new crop of granulocytes quickly comes back into the blood stream. If in this time of sepsis, the bone marrow reassumes its myelocytic activity, the first evidence in the blood stream is the finding of juveniles and band forms of the granulocytes, myelocytes and in one case myeloblasts. In case 10 myelocytes appeared in the blood two days before any juvenile granulocytes were seen. On the third day of regeneration there were 1350 leukocytes, of which 64 per cent were myelocytes, 8 per cent each of juvenile and band forms, and 20 per cent lymphocytes. Such a preponderance of myelocytes intimates nature's hurry to cure by the only known method—new granulocytes. Without them, sepsis does its perfect work through a blood stream infection, necrosis and gangrene, perhaps hemorrhage, intestinal ulceration, with or without a diarrhea, furunculosis, visceral abscesses, circulatory failure and a terminal bronchopneumonia. Here bronchopneumonia may better be regarded as a combination of localized pulmonary sepsis and circulatory failure.

TREATMENT

Acute incomplete granulopenia is as a rule a far milder condition than the usual fatal acute complete granulopenia. Some authors have not dis-

tinguished between the danger of the two conditions. All 12 of the cases reported in this paper showed an entire absence of granulocytes and were therefore acute complete granulopenias. Ten of the 12 are dead. Only two are living, both women, and one has had two attacks. As long as granulocytes remain in the blood stream, there is probably some myelocytic activity. The resumption of normal activity is a matter of degree of function and the prognosis is more favorable. Good nursing, food, water, fresh air and a watchful, expectant attitude may be all that is wise. The tendency is to do too much and to continue to do too much. Wise clinical judgment at the bedside is better than much long distance telephoning to distant authorities who boost a new and single specific remedy.

It is quite different with a complete granulopenia that comes with the sweep of a clinical storm. The mechanism and series of events in this degree of granulopenia are of ill import for recovery. Complete granulopenia is usually a fatal disease during the first or a later attack. We have not seen either of our two recovered cases return to normal, robust health. An absence of granulocytes in the blood stream means that the bone marrow has ceased its myelocytic activity and that collapse, fever, loss of immunity to bacteria and sepsis are at hand. One is called to treat far more than the apparently simple condition of absent granulocytes. Those who advocate and use specific remedies would do well to realize the enormous power they are claiming for the remedy. What is needed here is judgment of the therapeutic proof by the standards of scientific accuracy.

There are three chief objectives of scientific treatment.

- 1 The maintenance of the life and strength of the patient, much can be done with good nursing, food, air, water and care of the skin, throat, and control of fever.

- 2 The stimulation of the bone marrow to such a degree that it may resume its myeloblastic activity with the production of myelocytes and granulocytes. So far as we know, granulocytes do not function until they slip into the blood stream. There is apparently no known drug or specific remedy that can thus sufficiently stimulate the bone marrow.

- 3 The invitation to an early sepsis as nature's most universally used method to stimulate the myeloblastic activity of the marrow. It is the quickest way known to produce a leukocytosis. Nature uses it with telling effect in nearly all the purulent infections with pyogenic bacteria. The leukocytosis of appendicitis is an example. It is a myeloblastic stimulation that the surgeon calls a leukocytosis. There is no better way to provide it than the way nature provides it. We take the position that even complete granulopenia does not necessarily irreparably damage the marrow to the extent of destroying this important function. The function is in abeyance. After necrosis and sepsis we have seen the granulocytes rise in four days from none to 40,000. In another case with necrosis of the foot, in four days the granulocytes rose to 25,000.

With absent granulocytes and increasing sepsis, it is merely a question whether the patient can survive long enough for the granulocytes to reappear. Sepsis and necrosis are the great hopes of every patient with complete granulopenia. The patient may die from sepsis with maturation proceeding at full tilt in the marrow, but before the granulocytes reach the blood stream. It is well to avoid surgical treatment of the necrotic areas. Such treatment is of no avail until the granulocytes appear in the blood stream, and their reappearance will usually cure the patient and also the sepsis and necrosis.

With no evidence of sepsis and necrosis, one would not do far wrong to inject living staphylococci in the skin, or give 5 to 10 minims doses of turpentine intramuscularly. Kracke has shown that turpentine in this way causes necrosis of muscle tissue and a leukocytosis in the rabbit. One of us (S R R) used this method in one of our surviving cases apparently with a happy effect.

We have used radiation, transfusion, liver extract, pentose nucleotide and foreign protein to no avail. We have seen no result and only disappointment from their use. We have had no experience with adenin sulphate. We see no reason why it should be of aid.

DRUG IDIOSYNCRASY, WITH SPECIAL REFERENCE TO AMIDOPYRINE, AS A CAUSE OF AGRANULOCYTIC ANGINA *

By THOMAS FITZ-HUGH, JR., A M., M D., F A C P., *Philadelphia,
Pennsylvania*

THE designation, agranulocytic angina, although etymologically incorrect and scientifically inept, has become firmly entrenched—despite other preferable designations such as “pernicious leukopenia” or “primary granulocytopenia.” It is here employed, in the now generally accepted sense, as designating the syndrome of Schultz. This disorder was at first viewed as a peculiar reaction to some unknown infection, analogous to the previously recognized leukopenia sometimes encountered in overwhelming sepsis. Soon, however, it became clear that the heterogeneous micro-organismal invasion, seen in the majority of cases of agranulocytic angina, is merely a secondary or terminal event and is preceded by profound neutropenia. This led to the current view of agranulocytic angina as a clinico-pathologic entity of undetermined etiology belonging to the group of “blood system diseases”—to be distinguished from, although often simulated by, other types of neutropenia.

The possibility of an allergic mechanism in the etiology of agranulocytic angina has been emphasized in clinical teaching by O. H. P. Pepper since 1928 (after observing several patients afflicted with this disease whose histories indicated clear-cut allergic backgrounds). His first recorded statement of this hypothesis was made April 16, 1930, before the College of Physicians of Philadelphia¹ and was presented in greater detail in a Black Memorial Lecture² at Pasadena in January 1931. In a review of 18 cases of agranulocytic angina published in April 1933 Fitz-Hugh and Comroe³ stated that “additional treatment in all cases included oropharyngeal care, avoidance of drugs that might reasonably produce anaphylactoid reaction (Dr. Pepper’s suggestion), the use of orange juice, vitavose, calcium gluconate, and cod-liver oil.” Following the publication of this article with its specific reference to the possibility of “anaphylactoid” drug dangers, there appeared, quite independently, the epoch-making contribution of Madison and Squier⁴ presenting very strong evidence tending to incriminate amidopyrine medication with resulting allergic or anaphylactoid reaction as a most important cause of agranulocytic angina. Similar reports, altogether constituting a grave indictment of amidopyrine with or without barbituates, have since rapidly accumulated.^{5, 6, 7, 8, 9, 10}

* Received for publication June 23, 1934.

From the Department of Medicine, Hospital of the University of Pennsylvania.

The recent comprehensive review by Kracke and Parker⁹ of the hypotheses, experimental data, and clinical and laboratory findings relating to etiology makes unnecessary any general recapitulation. Since 1930 Kracke has maintained that drugs containing the benzene ring may be responsible for the disease and especially those belonging to the "benzamine group" amidopyrine, phenacetin, acetanilid, arsphenamine, neoarsphenamine. He has viewed this mechanism as a direct toxic action of some one or more of the oxidation products of benzene (hydroquinone, catechol, orthoquinone and paraquinone) on the bone marrow. His present position, however, includes the hypothesis of a "previously weakened, damaged, or idiosyncratic bone marrow" to account for the obvious facts that only a very few of the many individuals exposed to these substances actually develop the disease, and only an occasional experimental animal exhibits granulocytopenia out of a large group of animals given these drugs or their oxidation products.

In spite of the fact that our clinical staff has been for the past six years aware of the possibility of drug idiosyncrasy in agranulocytic angina and has frequently forbidden this or that drug in any given case where there seemed to be a suggestion in the patient's history of such drug's unfavorable or unusual action (including "allonal" in one early case!), we nevertheless failed completely to recognize the apparently important rôle of amidopyrine until the findings of Madison and Squier came to our attention a few months prior to publication of their paper. The purpose of the present report is to summarize the evidence accumulated in a review of our cases from the standpoint of drug idiosyncrasy, with especial reference to amidopyrine, as a possible cause of agranulocytic angina.

The following statistics and observations are based on a study of 26 cases of agranulocytic angina of which 18 have been previously reported.³ These data were obtained by study of recent patients, by review of hospital and office records, by personal conferences with surviving patients, and by correspondence with patients, relatives, and referring physicians.

The sequence of amidopyrine medication followed by hematologic proof of the diagnosis of agranulocytic angina is present in 14 cases (54 per cent). This same sequence is probably present but unproved in another five cases (19 per cent) and entirely unproved (but not impossible) in another six cases (23 per cent). The sequence is disproved in one case only.

In addition to the 14 proved instances of amidopyrine medication prior to hematologic verification of the disease (seven of whom continued the drug) there are three instances of amidopyrine medication instituted during the course of the disease. Thus 17 patients (65 per cent) are known to have ingested amidopyrine just prior to and/or during the course of the hematologically manifest stage of the disease. Of these 17 patients 13 are dead of the disease (77 per cent mortality) and four are living and well. Of the 13 fatal cases 10 continued and three discontinued ingestion of amidopyrine immediately after the establishment of the diagnosis. Of the

four surviving patients in this group three discontinued at once the ingestion of amidopyrine on establishment of the diagnosis and one discontinued it soon thereafter

Of the five cases listed as "probable but unproved" in relation to prior amidopyrine medication four are dead and three of these received amidopyrine during the course of the disease. Of the six "unproved" cases five died (all "acute cases") without receiving any amidopyrine after hematologic verification of the disease, although the possibility of prior amidopyrine medication can neither be affirmed nor denied with absolute certainty

The one patient in this series in whom amidopyrine medication can be absolutely excluded from all consideration will be discussed in some detail below. The total mortality figures to date are 19 dead (73 per cent), one of unknown status, and six living (three weeks' "cure," six months' "cure," eight months' "cure," three years' "cure," five years' "cure," and one relapsing case at present in good condition)

The preparations containing amidopyrine ingested by these patients are amidopyrine in capsule with other ingredients as prescribed by attending physicians, "pyramidon", "allonal", "peralga", "amytal compound", and "midol tablets"*. In no instance has the dosage of the drug been in excess of the average therapeutic limit. The largest quantity known to have been taken by any one of these patients was 25 grains daily of amidopyrine for seven days immediately prior to hospitalization, when the diagnosis was established. Two patients had used "allonal" and "pyramidon" at irregular intervals and in ordinary therapeutic quantity for several years before the fatal agranulocytic episode which seemed to follow just one more "ordinary dose". One patient had taken a few "midol tablets" for a few days each month for about six months prior to the proved onset of the disease. Another had taken only two "allonal" tablets and four "pyramidon" tablets during the period of 48 hours between a tooth extraction and the proved hematologic onset of agranulocytosis. Another, because of "acute tonsillitis," took a capsule containing two grains of amidopyrine every four hours for three days at the end of which period agranulocytosis was discovered. Our most recent case is that of a pupil-nurse who had taken one to two tablets of pyramidon once a month for about five years for relief of headaches. She had taken none, however, for at least a month until 5-29-34 when she took two tablets and repeated this dose (10 grains) on 5-30-34. Profound neutropenia was discovered on this date. A week later, after hematologic and clinical recovery, this patient was given

* A partial list alphabetically arranged, of proprietary and patented medicaments in which available evidence indicates an amidopyrine content includes "Allonal," "Alphebin," "Amarbital," "Amido-Neonal," "Amidophen," "Amifene," "Am-Phen-Al," "Ampydim," "Amytal Compound," "Baramid," "Barbromide" (Columbus), "Benzedo Compound," "Cibalgine," "Cincopyrine," "Compral," "Dysco," "Gynalgos," "Hexin," "Ipral-amidopyrine," "Kalms," "Lumordrin," "Midol," "Mylin," "Neonal Compound," "Neurodyne," "Optalidon," "Peralga," "Phenamidal," "Pyramidon," "Pyraminal," "Sal-Ethyl Carbonate Compound"

one five-grain tablet of amidopyrine with an ensuing loss of more than one-third of her circulating neutrophils in three hours, followed by prompt recovery

It is obvious that if amidopyrine-idiosyncrasy is a cause of agranulocytic angina we shall have to revise some of our concepts of the disease. In the first place the earliest symptoms of ill health, instead of being true "onset symptoms" of the disease itself in many instances must be viewed as purely accidental disorders which occasion the use of amidopyrine (or other drug) medication. This conclusion is predicated on the fact that several patients had taken no medicine of any kind for many months prior to the onset of distress symptoms which then, and then only, were met with drug (amidopyrine) administration and which seemed to merge promptly and imperceptibly into the ensuing picture of hematologically established agranulocytic angina. Such immediate symptomatic antecedents in these 26 cases are classifiable as follows: pharyngitis, tonsillitis, bronchitis, and "grippal" onset in 13 patients, dental extraction onset in five patients, gall-bladder colic onset in one, abdominal pain onset in one, kidney colic onset in one, postoperative (osteomyelitis) onset in one, neuritis and arthritis onset in two, carcinoma of bladder in one, migraine in three (one of whom is also included in the "grippal onset" group, and another in the abdominal pain group above).

A more fundamental adaptation of generally accepted views is involved in an interpretation of the mechanism of the known blood and bone marrow changes in agranulocytic angina if the drug-idiosyncrasy factor is to be accepted. The evidence in several "acute" cases mentioned above would necessitate the assumption of, first, an almost immediate granulocytoclastic crisis* occurring within a few hours to a few days of the first noxious dose of the drug, and second, a concomitant or subsequent bone marrow disturbance characterized by "maturation arrest" of the myeloid white cells at or below the myelocyte level and in many instances an apparently similar but less complete arrest, at the source, of lymphocyte and monocyte maturation and emigration¹¹. These two assumptions may be made without great violence to our preconceptions. The most difficult piece of evidence, however, to fit into the "drug-idiosyncrasy" hypothesis would seem to be the apparently established fact (Kracke et al.) that granulocytopenia precedes all other clinical phenomena of the disease. This fact would be understandable in the case of habitual users of the drug or drugs in question and would merely necessitate the assumption of suddenly acquired idiosyncrasy, or of previously existing mild and unrecognized episodes of agranulocytosis. It is also understandable in some acute cases if one accepts the hypothesis of certain supposedly early symptoms being merely reasons for medication rather than true onset phenomena of the agranulocytic angina syndrome. But the drug idiosyncrasy hypothesis and the now orthodox

* This term is coined to convey the idea that granulocytes suddenly disappear from the peripheral blood either by rapid elimination, destruction, or retention in internal organs and vessels.

dictum that "granulocytopenia precedes clinical symptoms" would seem to clash hopelessly in the face of certain acute and relapsing cases of the disease which have been reported^{12,13}

In these, and one of our own to be mentioned below in more detail, the neutropenia occurred out of a clear sky without drugs and with no symptoms requiring drug therapy until several days after the "agranulocytic" blood picture was established

That the role of amidopyrine in the etiology of agranulocytic angina is not a simple toxicologic process is obvious, not only from the fact that probably less than one in many thousands of users is afflicted with the disease but also from such considerations as the following (1) none of our patients with agranulocytic angina has taken an excessive quantity, (2) the records of two "allonal" suicides who lived four days and six days respectively, after taking between 30 and 50 tablets of allonal each, show essentially normal blood counts just prior to death, (3) the records of four private patients known for many years as habitual users of allonal (averaging at least two tablets nightly for at least three years) show repeatedly normal blood counts, (4) the records of two patients with measles and three with rheumatic fever each treated with amidopyrine in doses from 20 to 30 grains daily for from four days to three weeks show no granulocytopenia throughout

Other drugs used by our patients, before hematologic diagnosis was established, include aspirin, sodium salicylate, phenacetin, strychnia, phenobarbital, "amytal," sodium bromide, "salicon," "bromo-seltzer" (acetanilid), cinchophen, phenolphthalein, mineral oil, cascara, orthoiodoxybenzoate, quinine, and diphtheria antitoxin. Drugs used after diagnosis was established included many of the group just mentioned and in addition codein sulphate, morphine sulphate, digitals, caffein-sodio-benzoate, and the usual items of treatment of the disease itself (pentose nucleotide, blood transfusions, roentgen-ray, calcium, liver extract, etc., and in two cases neosphenamine)

The one patient in this series concerning whom it is certain that amidopyrine could have had no connection with his repeated bouts of agranulocytic angina is a man whose wife is a physician. This patient had taken a good deal of quinine in some of his attacks of probable agranulocytic angina prior to coming under our care. The important point in this connection, however, is that since then he has had several desperate attacks of "agranulocytosis" each one coming "out of a clear sky" without any medication of any kind (not even mineral oil which our records show to be a most frequent concomitant—though assuredly a blameless one)

This series, like others recently reported, shows a high incidence of patients closely related to practitioners of medicine: one dentist's daughter, one registered nurse, one pupil-nurse, one doctor's mother, one doctor's father-in-law, one dentist, one doctor's husband, two cousins of doctors, one doctor's wife

Six of the 26 patients gave histories indicative of definite allergy three with migraine associated with urticaria or eczema or vasomotor rhinitis, one with asthma, and two with food sensitizations. Two of these allergic individuals and three others (not obviously allergic) gave histories suggestive of drug idiosyncrasy (e.g., "stimulation" from morphine, "weak feelings" from aspirin, "elation and vertigo" from allonal, "depression" from phenobarbital). Skin sensitization surveys made in five cases showed only a few minor food reactions. Blood calcium studies in two patients during and after attacks of agranulocytosis showed no significant abnormalities. "Patch tests" with amidopyrine, acetanilid, acetylsalicylic acid, phenacetin, phenobarbital and morphine sulphate in one recently recovered patient (who had used pyramidon, bromo-seltzer and "empirin compound" for migraine prior to onset of agranulocytic angina) were all absolutely negative (Dr R. A. Kern). "Patch test" with amidopyrine in the most recent case—that of the pupil-nurse—was also negative.

It is clear that there are no valid tests or clinical guides to warn against the possibly noxious drugs in this agranulocytic type of idiosyncrasy, until the disease has already developed. It is then, unfortunately, sometimes too late—as evidenced by the fact that at least three patients, known to have taken amidopyrine prior to onset, and five, in whom there was no such evidence, died of the disease in spite of subsequent rigid proscribing of this and related drugs. The ordinary history of drug idiosyncrasy is untrustworthy at best and is often lacking in these cases. A clinical history of allergy, while possibly significant, is not obtainable in many patients with agranulocytic angina. Better methods of skin testing with drugs may eventually prove helpful but the evidence is not encouraging.

It is thus obvious that some presumptive evidence has been adduced in support of the thesis that amidopyrine idiosyncrasy may be an important cause of agranulocytic angina, but equally obvious that it is not the only cause. Kracke's findings would tend to incriminate any or all of his so-called "benzamine" group.⁹ In addition certain of the "heavy metals" have been suspected (especially gold). One case is now on record following dinitrophenol administered for "reducing" purposes.⁷ One of our cases developed during "oxoate" therapy. Several have been observed after intravenous typhoid vaccine injections and several after quinine administration (including one in this series). On the other hand the barbiturate group, at first suspected along with amidopyrine, has more recently been, at least in part, exonerated.^{14, 15, 16}

An analogous problem is raised in the recent report of thrombocytopenic purpura ascribed to "sedormid" medication in one instance¹⁷ and to "quinine and ergot allergy" in another.¹⁸

Closely related to amidopyrine is phenylhydrazine with its well known hematologic activity. We have never observed severe neutropenia, however, in the course of polycythemia vera under treatment with this drug. Other substances quite similar in chemical structure to amidopyrine and

phenylhydrazine are included in Kracke's "benzamine group" Each of these has from time to time in the past been observed to produce abnormal hematologic conditions other than granulocytopenia¹⁷

Personal records of blood counts obtained during certain ordinary acute drug idiosyncrasy reactions (one morphine-hyperemesis, several varieties of skin rash from iodide, arsphenamine, phenolphthalein, luminal, bromide and phenylhydrazine, two cases of salicylate and quinine tinnitus and one of belladonna sensitivity) show no instance of severe granulocytopenia comparable to true agranulocytic angina The same remarks apply to the leukocyte response in the more usual acute and chronic clinical allergies (bronchial asthma, hay fever, etc) Occasionally, however, severe neutropenia is found in acute serum sickness and in the early phase of protein shock It is also a nearly constant phenomenon of experimental acute anaphylactic shock (dog and guinea pig)

CONCLUSIONS

1 Our evidence suggests that amidopyrine idiosyncrasy may be a contributing "cause" of more than half the cases of agranulocytic angina In this series of 26 patients, 17 are known to have ingested amidopyrine just before and/or during the disease

2 A few well established negative instances, however, prove that amidopyrine cannot be accepted as the sole cause

3 Some of these non-amidopyrine cases may possibly be caused by idiosyncrasy to other drugs and substances (quinine, dinitrophenol, ortho-iodoxybenzoate, neoarsphenamine, bacterial vaccine, etc) or to a similar abnormal reaction ("anaphylactoid") to foods, exogenous or endogenous "toxins" whether chemical or bacterial, or to hormonal substances or a "conditioned deficiency"

4 If the causal mechanism be of idiosyncratic or allergic nature, it must represent a very special blood and bone marrow sequence of events hitherto unrecognized and different from the ordinary clinical and hematologic phenomena usually ascribed to such mechanism From the standpoint of leukocyte behavior the mechanism seems to be more like that of acute anaphylactic shock in laboratory animals than human allergy

5 The therapeutic implications of these findings suggest the advisability of more specific attempts at "elimination" and "detoxification" especially with regard to the liver²⁰ as a possible seat of allergic disturbances

DIAPHRAGMATIC HERNIA¹

By CARL A. HEDBLÖM, | M D, *Chicago, Illinois*

AN increased interest in diaphragmatic hernia has been stimulated by its growing incidence, by the sharp difference of opinion as to what constitutes one type of herniation at the esophageal hiatus, and by the marked recent increasing measure of success of its surgical treatment.

Diaphragmatic hernia is a protrusion of abdominal viscera through an anatomically weak area or through an abnormal opening or weak area in the diaphragm, the result of imperfect development, anatomical weakness or of trauma. A sac is a component part of a typical hernia, but the great majority of hernias through the diaphragm have no sac. By common usage they are classed as false diaphragmatic hernias.

The diaphragm is a thin, fibromuscular septum between the thoracic and the abdominal cavity. It consists of a peripheral muscular, and a central tendinous portion, and has three large openings, the esophageal, the aortic and the caval. The esophageal is the only one of the three through which hernias occur. It lies at the level of the tenth dorsal vertebra a little to the left of the midline, is oval in shape and is bounded by two muscle bundles from the crurae which rise on either side of the bodies of the upper lumbar vertebrae. The inner halves of these bundles cross one another between the aorta and the esophagus, and then pass to the central tendon. The size of the muscular ring so formed varies somewhat. Hernias occur in the gap bridged by pleura and peritoneum between it and the contained esophagus.

There are two triangular parasternal areas anteriorly, between the attachment of the muscle to the xiphoid and to the cartilages of the seventh ribs where there is a gap in the muscle bridged over by peritoneum (the foramina of Morgagni), through which diaphragmatic hernias occasionally occur.

There are two triangular lumbocostal areas between the attachment of the muscle to the vertebra and the twelfth rib, similarly lacking in muscle and through which a congenital hernia may develop (the foramina of Bochdaleki). After both these areas are protected from pressure by the upper poles of the kidneys and are therefore seldom the sites of an acquired hernia.

Abnormal openings or weak areas may be the result of incomplete or imperfect embryonic development of the structures dividing the single U-shaped celom into pleural, pericardial and peritoneal cavities. This is a complex process beginning in the human embryo 21 mm long. It is brought about through the fusion of several component parts as follows:

* Read before the American College of Physicians, Chicago, Illinois, April 16, 1934.
From the Surgical Department of the University of Illinois College of Medicine.
† Deceased.

(1) The dorsal mesentery, (2) the septum transversum, situated anterolaterally and ventrally, (3) the pleuro-peritoneal membranes, dorso-laterally, and (4) narrow shelves, peripherally, joining the parts from the pleuro-peritoneal membranes to the chest wall

These structures complete the division of the celom in the embryo of 18 to 20 mm. The muscular component between the pleura and peritoneum is of later, entirely independent origin. The muscle in the central portion at a still later period is replaced by the central tendinous structure. Failure of development of any part of one or more of these formative structures or failure of union of their adjacent parts results in a gap in the partition through which abdominal contents may later protrude into the pleural cavity without carrying before them any membrane or sac.

Absence of the muscular component at any point results in a weak area through which a hernial protrusion into the pleural cavity may develop. If the pleura and peritoneum representing the earlier embryonic structures are present they will form a sac for such a hernia. Similarly a hernia through the esophageal hiatus and at the foramina of Morgagni will have a sac.

Other embryological factors which may contribute to hernia formation are the development of the omental bursa and those factors incident to the relative sizes and changing positions of the stomach, intestines, and liver.

The omental bursae are two finger-like projections of peritoneum into the thick dorsal mesentery on either side of the foregut appearing in the embryo of 3 mm. Normally these projections become constricted off and disappear. If either of them remains open it constitutes a preformed hernia ring and sac.

The stomach originates as an enlargement of the foregut in the thorax in the embryo 11 to 12 mm long. It migrates downward with the elongation of the esophagus and coincident descent of the septum transversum and by the time the diaphragm is complete it normally lies below it. If any portion of it fails to reach its normal position at the time of diaphragmatic closure it will remain intrathoracic. We then speak of the condition as congenitally short esophagus and of a "thoracic stomach." The degree of esophageal shortening and the consequent amount of stomach that remains above the diaphragm vary. The esophagus may be so short that the whole stomach is intrathoracic.

The liver begins as an ingrowth into the septum transversum from the foregut. The anterolateral portion of the diaphragm proper is later split off from the main liver mass of the septum transversum by infolding of the peritoneum, the falciform and coronary ligaments in the adult representing the only portions that remain united. Abnormalities in liver development or in the later normal atrophy of the left lobe may lead to imperfect development of the diaphragm (Broman). Failure of physiological umbilical herniation of the intestines, which normally begins in the embryo 11 to 12 mm long, and which reaches its maximum in an embryo a little more than double that length, failing thereby to relieve increased

intra-abdominal pressure caused by the descent of the septum and rapidly enlarging liver within it, is said by some writers to be a factor in hernia formation

CLASSIFICATION OF DIAPHRAGMATIC HERNIA

Diaphragmatic hernia may be classified on an etiological basis as follows

- (1) Congenital (true or false),
- (2) Acquired (true or false),
- (3) Traumatic (true or false)

A congenital hernia as here understood means one present at birth. The absence of a sac indicates that the hernia opening is due to the failure of development or failure of fusion of one or more of the anlagen of the diaphragm. The presence of a sac composed of pleura and peritoneum is evidence of hernia formation after the complete separation of the pleural and peritoneal cavities.

An acquired hernia signifies one that develops gradually after birth in a congenitally weak area such as at the esophageal opening or at the parasternal or the lumbocostal trigone. It is acquired in the same sense as an inguinal hernia is usually acquired through the anatomically weak inguinal ring. With a few exceptions such hernias have a sac.

A traumatic hernia is one that results from a penetrating injury to the diaphragm, as by a bullet or a shell fragment or a knife stab, or from tearing or bursting of the diaphragm from sudden violent abdominal or thoracic compression, as from a fall, blow or crushing impact, almost all such cases are without a sac. Some writers have excluded recent injuries of the diaphragm with prolapse of abdominal contents, while including those of long standing as diaphragmatic hernia. There seems to be no reasonable grounds for attempting to so distinguish between identical conditions on the basis of duration.

Clinically the differentiation of these etiological types may be difficult. A hernia due to a gap in the diaphragm or one with a sac present at birth is obviously congenital but such a hernia may remain latent for years and then it may be difficult to decide whether it is congenital or acquired. Many writers include the acquired with the congenital. In the study of combined series of cases it is therefore expedient to combine these two groups. A traumatic hernia also may remain latent even if it produces symptoms or signs and may remain unrecognized for years. As a rule, its etiology is evident.

INCIDENCE

If the true incidence is to be deduced from the number of reported cases it is necessary that the diagnosis be certain. Up to recent years there could be no reasonable doubt as to diagnosis. Practically all the earlier reported cases were found at necropsy, a few were confirmed by operation. With the advent of roentgenography the demonstrations of herniation of various

parts of the gastrointestinal tract above the diaphragm also were unmistakable. However, during the last 10 years large series of cases have been reported of "herniation" through the hiatus of a small portion of that part of the stomach just below the terminal esophagus, the diagnosis having been based almost exclusively on a special technic for its roentgenological demonstration. The validity of this technic has been disputed by other observers.

In discussing the incidence of diaphragmatic hernia it therefore seems advisable to segregate the two groups.

The reported incidence of undoubted cases is shown in table 1.

TABLE I

Incidence of Diaphragmatic Hernia Exclusive of Large Series of Esophageal Hiatus Hernias

| Author | Con- genital | Acquired | Trau- matic | Total | Remarks |
|------------------------------|-----------------|----------|----------------|-------|-------------------------------------|
| Lacher | | 127 | 146 | 273 | Exclusive of 6 cases of eventration |
| Thoma (1882) | | 10 | 3 | 13 | |
| Grosser (1900) | | 98 | 48 | 146 | |
| Richards (1924) | 115 | 18 | | 133 | |
| Greenwald and Steiner (1929) | 60 | | | 60 | Exclusive of 22 reported elsewhere |
| Harrington | | 44 | 12 | 56 | 4 reported elsewhere |
| Hedblom (1931) | 116 | 133 | 351 | 600 | Including 26 personal cases |
| Hedblom (1934) | 64 | 36 | 27 | 127 | |
| | | 821 | 587 | 1408 | |

The incidence of "hernias" through the esophageal hiatus is given in table 2.

Åkerlund proposed a classification of esophageal hiatus hernias into three sub-groups: (1) those with a congenitally short esophagus producing the so-called "thoracic stomach," (2) the para-esophageal type in which the lower end of the esophagus remains fixed and variable amounts of stomach herniate through the ring along side of it, (3) those in which the lower end of the esophagus with more or less of the stomach prolapses through the opening—the "hiatus hernia" of Åkerlund.

"Thoracic stomach" is relatively rare. Only about 20 are reported. The para-esophageal, though generally accepted as a clinical and pathological entity, also seems to be relatively uncommon. The great majority of the cases reported belong to the third type. It has rarely been recognized at necropsy and has been overlooked on roentgenological examinations with

TABLE II

Incidence of Esophageal Hiatus "Hernias" Diagnosed Chiefly Roentgenologically and Largely Unconfirmed by Operation or Necropsy

| Author | Year Reported | Number of Cases |
|--------------------------|---------------|-----------------|
| Camman and Fineman | 1924 | 17 |
| Healy and Morrison | 1925 | 53 |
| Jenkinson | 1925 | 25 |
| Åkerlund, Ohnell and Key | 1926 | 25 |
| Pancoast | 1926 | 11 |
| Ude and Rigler | 1929 | 19 |
| Ritvo | 1930 | 60 |
| Berg | 1930 | 60 |
| Knothe | 1932 | 300 |
| Schatzki | 1932 | 23 |
| Velde | 1932 | 16 |
| Koeppen and Frank | 1932 | 20 |
| | | 629 |

the patient in the routine upright position. According to Åkerlund and others, who have reported large series of them, this is due to the usual spontaneous reduction of the herniated sac or its contrast media content, especially by gravity in the upright position. According to these writers its roentgenological demonstration requires that the patient be examined in the horizontal or partly inverted position and in some cases it also requires increased intra-abdominal pressure as produced by straining, by manual pressure, by constricting the abdomen, or by inflating the colon.

By such methods, Knothe, in von Beigmann's clinic, was able to demonstrate a "hiatus hernia" in 300 patients during one year, representing 8 per cent of all patients subjected to special gastrointestinal examination or such as were suspected of having a hernia. Koeppen and Frank found the condition in 20 (16.6 per cent) of 120 people, Velde in 16 (2.3 per cent), Schatzki, by inflating the colon to increase intra-abdominal pressure demonstrated the typical roentgen-ray in 23 (73.3 per cent) of 30 old people examined. It is thus evident that the proportion among different observers varies greatly.

The most direct evidence of the presence of a relaxed muscular and fibrous ring predisposing to herniation is offered by a series of observations, reported by Harrington, on 500 patients in whom the hiatus was palpated during the course of abdominal examination. He found the muscular ring snug about the esophagus in 65 per cent. In 35 per cent at least one finger could be insinuated between the muscular ring and the esophagus. In 5 per cent of this group three fingers could be inserted. All of this last group were subjected to special roentgenological examination for a hiatus hernia and "occasionally a small hernia was demonstrated."

The unprecedented number of cases reported by a few observers, many found in apparently normal individuals, the rarity of the condition in routine postmortem examinations, and the absence of confirmation of the roent-

genological diagnosis at operation or postmortem, except in a very few instances,* has naturally raised the question as to the validity of the roentgenological criteria on which the diagnosis of the hiatus hernia is based. According to Knothe these are (1) the recognition of the typical striations produced by gastric mucosa above the level of the diaphragm, (2) the constriction marking the border line between the stomach and esophagus lying above the diaphragm, (3) the shortening of the sub-diaphragmatic portion of the stomach, (4) the upper part of the stomach is displaced, the fornix disappearing, (5) the esophagus appears relaxed.

Some have interpreted the shadows in question as a normal dilation of the lower esophagus, denying that the folds are sufficiently distinctive to warrant the assumption that they are gastric. Others hold that there may be a shortening of the esophagus during swallowing with a consequent luxation of the part of the stomach just below the hiatus, but that the diaphragm in the immediate vicinity is also lifted into the form of a cone so that while a part of the stomach is lifted above the general level of the diaphragm, it still lies below the cone shaped part. As a result of further roentgenological, clinical, anatomical and pathological studies by Berg, Heinenheiser, Koppstein, Schatzki, Bergmann, Sauerbruch and his co-workers, Stadtsmüller and Creberg, Anders and Bahrmann and others a difference of opinion is evident as to the limits of the anatomical variation about the hiatus and as to the part that the physiological swallowing reflex plays in the production of the changes in shape and position of contrast media in the lower esophagus as observed under the fluoroscope. There is also a difference of opinion as to the significance of the changes produced by inspiration and expiration on the bolus of contrast media at the hiatus and as to whether or not the large striations seen in the roentgen-ray and characteristic of gastric wall are always a reliable criterion. Whether or not, under the various conditions of observation, there does exist an actual herniation of a small portion of the stomach through the hiatus, it seems pretty certain that such a hernia if present assumes practical importance only when it produces definite symptoms. In a great majority of cases any symptoms that may be present are mild and not with certainty referable to the condition.

LOCATION OF THE HERNIA OPENING

The location of the hernia opening was specifically mentioned in 728 of the collected cases of Lacher, Grosser, Richards, Greenewald and Steiner, and the author. In more than 78 per cent of the non-traumatic cases it was on the left side. Of this group more than one-quarter were at the esophageal hiatus, about the same proportion posteriorly and about one-sixth were central. Of the 22 per cent on the right side, about one-quarter were centrally situated, about one-quarter were posterior and nearly one-third at the parasternal foramen.

* Åkerlund reports eight of his original series confirmed later by necropsy.

Of the traumatic hernias, about 95 per cent were on the left side, nearly one-half were lateral and nearly one-quarter central, half of those on the right side were central

Half of the bilateral hernias were at the parasternal opening. So-called bilateral esophageal hernias usually involve a bilateral distribution of the sac through a common opening

Hernias at the parasternal opening are of special importance from the standpoint of surgical treatment. Those with a sac through the foramen of Bochdaleki are uncommon. A sac was present in only four of 60 children and in six of 19 adults in whose cases its presence or absence was mentioned. Those posteriorly situated without a sac are due to failure of closure of the pleuroperitoneal membranes and so are present before the development of the foramen of Bochdaleki. They are therefore not through this foramen

About one-quarter of the non-traumatic hernias situated centrally had a sac indicating a faulty development either of muscle or of later tendon formation in this region rather than a failure of closure or union of the anlagen of the diaphragm. The instances of subtotal or total absence of the diaphragm were mostly necropsy findings in infants. A small proportion survive to adult age

The hernia contents may be a single abdominal viscus or may include any or all the abdominal organs except those in the pelvis. In a series of 857 cases there were 72 different combinations of herniation of the stomach, intestines, colon, omentum, spleen, liver, pancreas and kidney. The stomach alone was herniated in 160 cases (20.0 per cent), the colon alone in 86 (10.3 per cent), the omentum alone in 65 (9.5 per cent), the liver alone in 14 and the spleen alone in two

A typical esophageal hiatus hernia contains usually the cardiac portion of the stomach, one at the parasternal foramen, a loop of transverse colon. In a right-sided hernia except those at the esophageal hiatus and parasternal foramen the hernia content is usually some portion of the liver

ETIOLOGY

There seems to be no sex predisposition to congenital hernia. In a series of 124 infants the sex distribution was equal. There is a preponderance of females with acquired hernia at the esophageal hiatus, nine-tenths of traumatic hernias are in males

There is a marked difference in age incidence of the different types. Of the congenital hernias included in a series of 743 cases about one-third died before reaching one month of age. The great majority of patients with acquired hernias are past middle age, when the hernia is recognized. More than two-thirds of the patients with traumatic hernia are in the second, third and fourth decades of life

Among the congenital cases there is a frequent association of other anomalies of development such as harelip, cleft palate, patent ductus ar-

teiosus of foramen ovale, abnormal or imperfect development of lung, liver or of mesenteric relationships, abnormal cranial development and monstrosities of various types

The direct cause of congenital hernia openings is faulty development of the diaphragm, the specific cause of which is uncertain. It seems reasonable to believe that any one or more of a number of factors involved in the growth and shifting relationships of the anlagen of the diaphragm and of the adjacent organs may contribute to its imperfect or incomplete formation, but the frequent coexistent anomalous development elsewhere suggests the presence of a more general cause.

The most manifest direct cause of hernia formation through the esophageal hiatus, the parasternal foramen and through other areas deficient in muscular support is probably increased intra-abdominal pressure, such as that due to straining at stool, or during micturition, coughing, vomiting, labor, or due to a sudden muscular straining or sudden wrench. Mechanical factors that increase intra-abdominal pressure such as pregnancy, kyphosis, megacolon, have been repeatedly observed in relation to hernias of this type.

Weakening of the diaphragm muscle and absorption of fatty deposit between the serous membranes (in esophageal hernia) are believed to contribute to hernia formation especially in women.

Traumatic lesions may be due to penetrating injuries or blunt trauma. In a series of 318 civilian traumatic cases 165 (52 per cent) were due to penetrating injuries and 153 (48 per cent) to blunt trauma. Of the penetrating injuries 116 (20.3 per cent) were stab wounds, 35 (21.3 per cent) gunshot wounds and eight followed operation for empyema, at least some of which were probably due to operative injury to the diaphragm. Two cases were associated with fractured ribs. Of the non-penetrating injuries 66 (36.6 per cent) were due to falls, 35 (22.8 per cent) to crushing impact, 15 (10 per cent) injuries of the "jack knifing" type by falling weights. In 16 instances some type of violent strain was given as the cause.

In a series of 127 hernias due to war injuries, 44 were due to bullets, 32 to shell fragments and two to bayonets. In 49 the cause was not stated.

SYMPTOMS

There is no entirely characteristic symptom or syndrome. There is a great variation in the symptoms produced by the same type, as well as by different types of hernia. Age incidence, pathogenesis and pathological anatomy determine certain group characteristics, but a hernia of any type may remain symptomless, being discovered at operation for other conditions or at necropsy. The first symptoms in a hernia of years' duration may be those of an acute obstruction.

Symptoms caused by the hernia are often misinterpreted, and the patient treated on the basis of a false diagnosis. The importance of familiarity with the varied clinical manifestations lies not so much in that it will lead

to a diagnosis independently as in that it will suggest the necessary further study to establish the diagnosis

The symptoms naturally group themselves into those referable to the thorax and to the abdomen, respectively. The size and position of the hernia contents determine in large measure the thoracic symptoms, and the hernia content and differing degree of hernia ring constriction account largely for the wide range of abdominal symptoms

Dyspnea, cyanosis, palpitation and a feeling of fullness or of suffocation, dysphagia, pain under the sternum and in the shoulder, and coughing are the most common thoracic symptoms. Hiccough is occasionally present. Dyspnea, palpitation and a feeling of fullness occur most characteristically after heavy meals or after drinking a large amount of fluid. Many patients are unable to lie down immediately after meals on account of such symptoms. Some induce vomiting or pass a stomach tube on themselves for relief of this distress. Some patients speak of a subjective feeling of the presence of fluid, of gurgling or of splashing in the thorax, others of a sense of impending disaster in connection with a feeling of suffocation. Some patients have more difficulty swallowing liquid than solid food.

The most characteristic abdominal symptoms are those of indigestion of a character more or less suggestive of peptic ulcer or of gall-bladder disease. Nausea and vomiting are common, hemoptysis and melena occasional.

Certain types of hernia have fairly characteristic symptoms. An acquired hernia at the esophageal hiatus usually produces only mild symptoms of indigestion, or more or less dysphagia, but there may be a variety of symptoms of severe grade, including such as are very suggestive of angina pectoris.

Hernias of the parasternal opening containing most often a loop of colon are characterized by constipation and colicky pains. If the loop of herniated bowel is large there may be dyspnea, a sense of suffocation and palpitation.

The immediate symptoms of a traumatic hernia may be due to the injury as such—shock, hemorrhage, pneumothorax. The later symptoms are determined largely by the size, shape and position of the hernia opening and by its content.

Symptoms of obstruction when present are similar to those due to other causes, but an associated dextrocardia and retracted abdomen are almost diagnostic of diaphragmatic hernia as cause of the obstruction.

PHYSICAL FINDINGS

The physical changes produced by diaphragmatic hernia are chiefly thoracic and due to the pressure of the abdominal viscera in the thorax. A bulging of the thorax and decreased respiratory excursion on the affected side, changes in the percussion note and in the auscultatory findings suggestive of pneumothorax, or of a pleurisy with or without effusion, or of

pulmonary cavitation are the most common. A variation of the physical findings, particularly those of auscultation and percussion following change in position and following the taking of fluid or food, is very suggestive of hernia. Borborygmi over the thorax is pathognomonic if eventration can be excluded. Cardiac displacement is very common. A scaphoid abdomen is occasionally observed.

DIAGNOSIS

Before the advent of roentgenography the intravital diagnosis of diaphragmatic hernia was rare. Bowditch in 1854 made the first diagnosis in the living. Lichtenstein in 1874 wrote that of 345 cases he had collected up to that time, only two cases had been recognized clinically, and he reported the first case diagnosed on purely objective grounds. In 1912 Giffin collected 650 cases, among which the diagnosis was made during life in only fifteen.

With the more general use and greater efficiency of roentgenological examination, an increasing proportion are diagnosed clinically but often only after the hernia has been present for many years. Of 82 cases in children collected by Greenewald and Steiner, intravital diagnosis was made in 27, but in only six clinically, 21 were diagnosed by routine roentgenological studies, 47 were found at necropsy, four were diagnosed at operation.

Traumatic hernias are often overlooked. Of 127 soldiers wounded in the late war who were later found to have traumatic hernia, over 40 per cent had symptoms for one to 15 years before the diagnosis was made. A large number of cases are recorded of acute obstruction, years after penetrating injury or blunt trauma, found at operation or necropsy to be due to diaphragmatic hernia.

Symptoms and signs as described, referable to the thorax and abdomen, not accounted for on other grounds, especially with a history of trauma of severe grade or in the presence of scars of a penetrating injury of the lower thorax, should always suggest the possibility of diaphragmatic hernia.

ROENTGENOLOGICAL DIAGNOSIS

Positive diagnosis usually rests on the roentgenological findings. The ordinary fluoroscopic or roentgenographic examination may furnish very strong evidence in the form of localized areas of rarefaction or of consolidation suggesting localized pneumothorax, pleuritis, eventration, hydro-pneumothorax or of multiple cavities in the lung. Positive proof usually rests on the demonstration of a portion of stomach or bowel above the diaphragm following a barium meal or enema. The conditions which simulate hernia most closely on such roentgenological examination are esophageal diverticulitis and eventration of the diaphragm.

Esophageal diverticulitis is usually distinguishable by fluoroscopic demonstration of the filling of the diverticulum first, whereas in hernia of the

stomach through the esophageal hiatus the opaque medium passes through the cardia into the abdominal portion of the stomach and then into the herniated portion

Eventration may be very hard to differentiate. It requires the demonstration of the crescentic shadow of the eventrated diaphragm above the abdominal viscera, the immobility or paradoxical respiratory movement of the affected half of the diaphragm and the identification of the gas or contrast media filled stomach under it.

Failure of demonstration of the stomach or bowel above the diaphragm does not exclude the possibility of hernia. The hernia protrusion may be spontaneously reduced at the time of the examination, or the contrast medium may fail to enter the herniated portion, or a solid viscus only (omentum, liver, spleen) may be herniated.

As stated above a herniated portion of the stomach or a small real esophageal hiatus hernia is usually spontaneously reduced when the patient assumes the upright position, and such hernias therefore are usually overlooked in routine roentgenological examinations. Spontaneous reduction may occur also in other types. Examination for diaphragmatic hernia should therefore be made in the horizontal or Trendelenburg position.

The differential diagnosis of diaphragmatic hernia involves consideration of the commoner abdominal disease conditions such as peptic ulcer with its sequelae, carcinoma of the esophagus and of the stomach, gall-bladder disease and partial or complete obstruction from any cause, and also those conditions of the thorax giving somewhat similar physical findings, such as pleuritis with or without effusion, pneumothorax, pulmonary cavitation, and angina pectoris.

COMPLICATIONS

The most common complications are acute intestinal obstruction and its sequelae, and acute respiratory failure. Gastric ulcer is common. Shock and hemorrhage are especially associated with the trauma causing rupture.

The transverse colon is the portion of the bowel most often strangulated from constriction in a small hernial ring. Either large or small intestine, however, may become gangrenous and perforate due to obstruction of blood supply as a result of volvulus or torsion.

Acute respiratory failure as mentioned is most common in infants with congenital hernia, but may occur in adults with hernia of any type. Many cases of sudden death from asphyxiation are recorded (Fishback, Granzow). The herniated stomach or bowel may be enormously dilated.

TREATMENT

The treatment of diaphragmatic hernia is surgical repair. Relative unfamiliarity with the condition, uncertainty of diagnosis, the frequent technical difficulties incident to its surgical repair and the relatively high

postoperative mortality in the past have combined to create in the medical profession an attitude of false conservatism with respect to surgical treatment. Postoperative deaths from obstruction have been unjustly attributed to the operative procedure.

The mortality in obstructed cases is about two and one-half times that of those operated upon before this complication has developed. A great many instances are recorded in the literature of persistent expectant treatment in the face of recurrent attacks of symptoms characteristic of impending obstruction, which finally developed, the patient dying from it, not infrequently after an operation performed in extremis.

Many patients are allowed to drag on indefinitely as semi-invalids, some incapacitated by nervous instability, some reduced to living skeletons from inability to swallow food or from persistent vomiting.

INDICATIONS FOR OPERATION

The indications for operation should be considered in terms of the severity and gravity of the symptoms as such and in terms of the relative danger of complications and of operation in any given case.

The possibility of saving many of the infants with congenital hernia is suggested by reported successful cases. Since 1931 there are reported nine cases of infants under one year of age operated upon for the repair of the hernia. Six (66.6 per cent) recovered, in one case the opening was too large for closure, two died, one of nine months, and one "new born." One cured case operated upon by Carylles was 13 days old, one successfully operated upon by Johnson and Bower was forty-one and a half hours old. This, it is believed, is the youngest case on record. Five cases between five and 10 years of age and one 13 years of age were cured.

Most congenital hernias in older individuals are posterior or posterolateral. The opening may be assumed to be small if only a part of one viscus is herniated. If a large portion of the abdominal viscera are herniated it still may be small, but it is likely to be relatively large. If the opening is too large for primary closure it may be closed by a muscle or fascia plastic procedure, or by preliminary thoracoplasty combined with some plastic repair.

An acquired hernia ring at the esophageal hiatus may be relatively inaccessible and the edges of the ring may be ill defined, making the closure difficult. If the hernia is small and producing no marked symptoms, operation is hardly indicated, but if relatively large or producing rather marked symptoms it should be repaired.

Acquired hernia at the parasternal opening usually produces relatively severe symptoms due to partial obstruction of the colon and to crowding of the heart and lungs. The hernia opening is quite accessible through an epigastric incision. Such a hernia should be repaired unless there are very definite contraindications to operation.

Penetrating injuries in the chest wall from the sixth interspace down should be explored for injury to the diaphragm and abdominal viscera if there is any probability of deep penetration. If symptoms persist following severe blunt trauma, and roentgenological examination shows hernia, immediate repair is advisable.

Preliminary operations include enterostomy, phrenic nerve crushing and thoracoplasty. An enterostomy may be life saving in acute obstruction, the hernia being repaired at a later date. Phrenic nerve crushing will facilitate the closure of a large hernia opening centrally or peripherally situated. In case of an esophageal hiatus hernia it is of less value and in case of a parasternal hernia it is not necessary and may be harmful in that it is impossible to determine clinically through which parasternal opening a right or left sided hernia sac protrudes.

Preliminary thoracoplasty is indicated if clinical study or exploratory operation has disclosed an opening too large for direct or plastic closure.

Among 57 cases reported during the last three years the immediate result was good in 72 per cent. There were eight deaths (14 per cent). In the author's series of 22 cases operated upon there were two operative deaths, one from infection, and one, a puny child of four and one-half years, from shock.

SUMMARY

1 Diaphragmatic hernia may be present at birth, it may be acquired through anatomically weak areas, or it may result from direct injury to the diaphragm, or from sudden accidental greatly increased intra-abdominal pressure.

2 There is an increasing incidence of reported cases, particularly of those of the acquired type at the esophageal hiatus and of those incident to wounds and automobile accidents. The greatest increase in incidence is that of the small so-called reducible hiatus hernias demonstrable only by special technic of roentgenological examination, and the inclusion of which as diaphragmatic hernia is challenged by many observers.

3 The exact etiology of the congenital type is not known, that of the acquired type is chiefly increased intra-abdominal pressure in the presence of a congenitally weak area of the diaphragm or an acquired weakness due to atrophy of muscle and absorption of fat deposit in the anatomical foramina.

4 The symptoms are referable to the thorax or abdomen or both in varying proportions and degree. The thoracic symptoms are due largely to interference with the functions of respiration or circulation or both. Abdominal symptoms are largely attributable to a greater or lesser degree of obstruction of stomach or bowel.

5 The physical findings are chiefly thoracic and due to the presence of the herniated viscera. Borborygmi, partial dextrocardia and variable physical findings, especially with changes in position, are particularly significant.

6 The diagnosis is confirmed by the demonstration of an abdominal viscus above the diaphragm. A gas filled viscus may be recognizable, one containing a contrast medium, except in case of a hiatus hernia, is unmistakable. Failure to demonstrate a hernia does not exclude it.

7 Small, reducible, symptomless hernias at the esophageal hiatus should be treated expectantly. The treatment of all other types is surgical repair unless contraindications are present outweighing the indications for operation in the individual case.

8 Intestinal obstruction is the most serious complication and operation in its presence more than doubles the operative mortality.

9 Among 57 cases operated upon, reported during the last three years, there were eight deaths, a mortality of 14 per cent.

10 In the author's series of 22 cases operated upon there were two operative deaths, one from infection, and one, a puny child of four and a half years, from shock.

THE "Q" DEFLECTION IN NORMAL AND ABNORMAL HUMAN ELECTROCARDIOGRAMS*

By CHARLES SHOOKHOFF, M D , and ALBERT H DOUGLAS, M D ,
Brooklyn, New York

SINCE Pardee,¹ in 1930, re-directed attention to the Q-wave and reported a relative frequency of large Q's, in cases that showed coronary artery disease, there has been an increased effort directed toward the determination of the significance of Q and, more particularly, of a large Q₃. All such work in the Q-wave has been based on the assumption that the term Q, or Q₃, designates a more or less definite part of the electrocardiogram, and that it probably refers to the activation of a fairly definite part of the heart. In this paper we shall attempt an analysis of the Q-wave in normal records and in records of the large Q₁ type that will indicate the relative time occupied by Q. We feel that this time data throws light on the significance of the large Q-wave.

METHOD

For the identification of the parts of the ventriculogram in the three standard leads that correspond in time we have made use of Einthoven's formula as follows: when on any and every vertical line the electrocardiographic curve can be superimposed so that the height in Lead I added to that in Lead III gives the height in Lead II, the time relations are identical.

In all electrocardiograms studied we measured the size of positive deflections from the top of the base line and that of negative deflections from the bottom of the base line. When the figure for Q₁ algebraically added to that for Q₃, gave, with reasonable accuracy, the height of Q₂, it was assumed that Q₁, Q₂ and Q₃ occupied the same time interval. When the size of Q₂ differed grossly from the algebraic total of Q₁ and Q₃, it was assumed that Q₁, Q₂ and Q₃ did *not* occupy the same time interval. Similar calculations were used for R and S. When Einthoven's equation did not balance for one wave, e g , Q₁ plus Q₃ greater than Q₂, while the algebraic total of *all* deflections in Lead I added to the algebraic total in Lead III gave the total in Lead II ($(Q_1 - Q_3) - (R_1 - R_3) - (S_1 - S_3) = (Q_2 - R_2 - S_2)$), it was concluded that summation had taken place so that one wave corresponded to either more or less of the time part occupied by the wave of the same name in another lead—Q₃ for example, corresponding in time to Q₁ plus part of R₁.

* Received for publication May 7, 1934

From the Division of Cardiology, "B" Medical Services, the Jewish Hospital of Brooklyn

The method outlined above enables one to identify peaks that coincide in time in the three standard leads of an electrocardiogram, and, when they do not coincide, to find the points in the other two leads that do correspond in time with a given peak. In figure 2A, for example, the peak of Q_3 corresponds in time with R_1 and we, therefore, conclude that Q_3 and R_1 represent the same moment and the same process in the heart.

NORMAL ELECTROCARDIOGRAMS

We analyzed electrocardiographic tracings taken from 28 student nurses at the Jewish Hospital in whom there was no clinical evidence and no history to suggest the possibility of heart disease. Three of these records showed a deviation of the main axis to the left, including one large Q_3 and one small Q_3 . Twenty-five of these records showed a normal axis deviation. The Q, R and S waves appeared to occupy the same time interval in 14 of the group of 25 (56 per cent) (Table 1). In the other nine cases Q_1 plus Q_3

equalled Q_2 in six (table 2). In all, therefore, Q_1 , Q_2 and Q_3 appeared to occupy the same time interval in 20 of 25 tracings (80 per cent). There were four records with no Q-wave. If these are omitted, Q_1 , Q_2 and Q_3 appeared to agree in time in 16 of 20 tracings (80 per cent). The five cases in which Q_1 plus Q_3 did not equal Q_2 are presented in table 3. In these there appeared to be summation so that Q in one lead corresponds to Q plus part of R in another lead. Q, however, is small in all of these five curves and occupied, at most, insignificant parts of the time taken in other leads by the first part of R. *These results suggest that for practical purposes the term Q represents a definite time interval in normal electrocardiograms.* Examination of the S-wave in this series of normals revealed

| 8 | 0 | -0.5 | -1 | +2.5 | +8 | +8 | -2 | -0.5 | -0 |

gross lack of correspondence between S_1 , S_2 and S_3 in eight of 25 tracings (32 per cent). In some of these tracings S was large (up to 57 per cent of the height of the largest deflection) and could include significantly large parts of the curve that would correspond in time to R in other leads. These results indicate that S cannot be regarded as representative of a definite time division in normal electrocardiograms.

ELECTROCARDIOGRAMS WITH A LARGE Q_3

In an examination of 1200 consecutive electrocardiograms taken at the Jewish Hospital, 50 (4 per cent) were found which show a large Q_3 according to Pardee's criteria, i.e., Q_3 represents 25 per cent or more of the maximum deflection of Q - R - S , and there are no S_3 's. Waves of the M and W types are omitted. The size of each deflection in this series is given in tables 4 and 5.

Analysis of these records in the manner in which the normal records were analyzed shows that there is no algebraic relation between the total of Q_1 and Q_3 and the height of Q_2 , or between the total of R_1 and R_3 and the height of R_2 , or between the total of S_1 and S_3 and the height of S_2 . A relationship does appear, however, when the algebraic total of all waves in Lead I is added to that for all waves in Lead III. The grand total obtained approximates more or less closely the algebraic sum of the deflections in Lead II.

It appears evident from the data given that the Q-waves in the three leads do *not* correspond in time. In other words Q in these cases is not identical in time with Q₁ and Q₂ but represents a summation of the time represented by these deflections with varying amounts of the time taken by R₁ and R₂. Thus, in 30 of the 50 records studied (60 per cent) Q corresponded in time with parts of R₁ or R₂ in addition to Q₁ or Q₂ (see table 4). In 20 (40 per cent) Q occupied more or less accurately the same time interval as that occupied by R₁ or R₂ (see table 5). In *none* of these electrocardiograms did Q occupy the same time interval as that occupied by Q₁ and Q₂. The larger Q₁ became, the less did it agree, as far as timing was concerned, with Q₁ and Q₂ and the more with R₁ and R₂. (See figure 4.)

Figures 2 and 3 illustrate the two types of large Q₁ described above and represented in tables 4 and 5 respectively.

DISCUSSION

The data presented indicate that the Q-wave may be a physiological entity, in the sense that it may represent a fairly definite time interval and the activation of particular parts of the ventricle, only in normal ventriculograms. In abnormal ventriculograms the Q-wave represents markedly different time parts—both in the different leads of a single electrocardiogram and in different electrocardiograms. In the light of this finding it appears to us wrong to speak of Q, or of the initial deflection of the Q-R-S complex, or even of the Q of a definite lead, such as Q₁, as representative of activity in different portions of the ventricle. Since different Q₁'s can occupy grossly different time divisions of the ventriculogram they can, it seems to us, represent activity in different parts of the ventricle.

There appears to be, instead of one, three possible types of Q₁ waves, as follows:

- 1 Those that correspond in time with Q₁ and Q₂,
- 2 Those that correspond in time to Q₁ and part of R₁,
- 3 Those that correspond in time, more or less accurately with R₁.

A study of tables 4 and 5 in accordance with this division shows that none of the large Q₁ waves are of type 1, most are of type 2, and many are of type 3. In other words, the large Q₁ waves are not comparable with the normal Q₁ wave which belongs to the first type. Figure 1 illustrates Q₁ waves of the first type described, figure 2 illustrates the second type, and figure 3 the third type.

It appears clear that the large Q₁ wave, which corresponds with part or all of R₁, cannot be produced by the mechanism which causes the small normal Q-wave. The theories of Lewis² and Wilson³ of the causation of the normal Q-wave apply at most to only part of the large Q-wave. Several authors have undertaken, nevertheless, to explain the large Q-wave

by these theories. Paidee,¹ for example, quoted Lewis'⁴ concept of the normal Q-wave to support a belief that the large Q₁ represented activity in the right ventricle.

Recently Fenichel and Kugell⁵ have attempted a correlation of large Q-waves with pathological observations. They assume that they are referring to a more or less definite time part when they speak of the large Q-wave and conclude that it is caused by disturbance in the intraventricular septum—chiefly in the left half, posteriorly. We have shown that a large

FIG. 1 Small Q₃'s which correspond in time with Q₁ and Q₂

Q₁ corresponds in time with all or part of R₁ and R₂. To accept Fenichel and Kugell's explanation of a large Q₁, one would have to conclude that R₁ and R₂ in these electrocardiograms, similarly, are, at least in part, due to septal disturbance. One would then have to explain the absence of suitable electrocardiographic representation for the rest of the ventricle. Fenichel and Kugell offer no such explanation, nor for the reduction in the size of R₃ as Q₁ gets larger, or for the usual absence of S₃ in records of the large Q₃ type. It appears to us that septal disturbances may cause changes in the initial time part of some abnormal ventriculograms, but that they

FIG 2 Illustrating large Q_3 s which correspond in time with Q_1 plus part of R_1

Fig 3 Large Q_i 's which correspond in time with R_i

cannot by themselves explain those large Q_1 's which represent almost all of the activation phase of the ventriculogram (figure 3). In the hearts studied by Fenchel and Kugell, pathological changes were not limited to the septum and it appears to us probable that pathologic lesions in the ventricular wall, rather than in the septum, produced most of the large Q_1 waves in their series.

We wish to emphasize at this point that in records of the large Q_1 type, the *entire* Q - R - S , not Q alone, is altered in rather a characteristic way, i.e., as Q_1 becomes larger, R_1 becomes smaller and S_1 disappears. (See figure 4.) (At times in these records P_1 becomes inverted¹⁷.) These facts should be borne in mind in the following discussion. They suggest a change in the spread of the excitation wave in the ventricle as a whole, rather than in a limited portion of it. Figure 4, an indifferent series of electrocardiograms with large Q_1 waves, indicates that the *larger* Q_1 *becomes*, the *smaller* does R_1 *become* and the more does Q_1 correspond in time with R_1 . The Q/R ratio of the first electrocardiogram presented, in which Q_1 is normal, is practically the reverse of the Q/R ratio in the last electrocardiogram of figure 4, in which Q_1 is large. The fact that Pardee¹ found S_1 so infrequently associated with a large Q_1 is explainable, at least in part, by the fact that in many tracings with a large Q_1 , the small R_1 present corresponds in time with S_1 and represents the same ventricular activity that S_1 represents. A study of the changes that respiration causes in the relation of the Q , R and S waves, one to another suggests an interdependence so that when one wave varies, the others also change in characteristic fashion. (See figure 5.) The same relationship is found when a large Q is produced in pregnancy.^{1,6}

We regard as significant the work of Meek and Wilson⁷ who produced a large Q_1 by rotation of a dog's heart about its longitudinal axis to the left and a large Q_1 by rotation of the heart about its longitudinal axis to the right. Their observations agree with the clinical finding of a large Q in the A-P lead in normal individuals when the right arm electrode is placed anteriorly and the left arm electrode posteriorly—an arrangement which represents a relative rotation of Lead I 90° to the left (around a longitudinal axis) or of the heart 90° to the right. (See figure 6.) As the right exploring electrode is shifted toward the left, the Q -wave becomes larger and the R relatively smaller. This is illustrated in figure 17B (precordial leads) of Wilson, et al.,⁸ as well as in our figure 6B.

We believe that the assumption that a large Q is caused chiefly by rotation of the ventricular electrical axis about a longitudinal axis can explain all the known facts about a *large* Q . Such rotation could be caused

- (a) By mechanical factors that change the position of the heart,
- (b) By a change in the position of the leads, causing a relative rotation of the heart,
- (c) By damage to part of the ventricular musculature with collapse, the contraction of scar tissue or the dilatation of a damaged area,
- (d) By thickening of one part of the ventricular musculature

FIG. 4. Shows that as Q_2 gets larger it corresponds more with R_1 and less with Q_1 . Note the occasional inversion of P in these tracings.

FIG 5 This is the third lead of a curve showing the changes in the relationship of the Q and R in the respiratory phases. The three strips are continuous

Pardee¹ and others^{8, 9, 10, 11} found a large Q, most commonly associated with coronary artery disease—cases of hypertension, arteriosclerosis or aortitis. In this type of case the outstanding pathology consists of damage to the ventricular musculature that is more or less diffuse but is most marked

FIG 6 (A) The three conventional leads of a normal individual, from whom the posterior-anterior leads (B) were taken (B) Anterior-posterior leads, with the left electrode placed slightly to the left of the spine, at the mid-scapula level, and the right arm electrode in 1 placed to the right of the right border of the sternum in the fourth space, 2—at the left border of the sternum, 3—at the midclavicular line, left, 4—in the anterior axillary fold at the same level. Note the increasing depth of the Q-wave and the changing relationship of the Q to the R as the exploring electrode is moved to the left, being the equivalent of an increasing rotation of the heart to the right on its longitudinal axis

in the left ventricle—degeneration due to ischemia, or infarction with an inflammatory reaction and connective tissue replacement. It does not appear to be far fetched to postulate that collapse of necrotic heart muscle, traction due to scar tissue or dilatation of weakened areas may be causes for a relative rotation of the electrical axis about a longitudinal axis. That large Q's are occasionally found in normal adults, and with greater frequency in normal infants (Kumbhaar and Jenks¹² and Seham¹³), and in pregnant women¹ appears consistent with our thesis. The relative frequency of a large Q₁ in cases of pericarditis¹ is also explicable by the assumption of a longitudinal rotation of the electrical axis.

The application of this theory to the findings of Wilson and his co-workers⁸ suggests that the large Q₁ found with infarction of the anterior and lateral wall of the left ventricle, secondary to occlusion of the descending branch of the left coronary artery, may be the result of a collapse of the necrotic tissue with a rotation of the electrical axis about a longitudinal axis to the right. Similarly, collapse of a dead area on the posterior wall (caused by occlusion of the circumflex branch of the left coronary artery) might produce a large Q by a rotation of the electrical axis about a longitudinal axis to the left. Exceptions to the rule could be the result of dilatation of weakened areas, rather than collapse, with ensuing longitudinal rotation in the opposite direction. A clear illustration of this is given in figure 7. This figure shows a definite Q₁ T₁ group. Clinically the patient presented definite signs and roentgenologic findings of an aneurysmal dilatation of an acute myomalacia which could very well have caused a relative rotation of the left ventricle about a longitudinal axis to the right (Shookhoff and Douglas¹⁴).

In considering the significance of a large Q₃ it is interesting to recall the history of our interpretation of a large S₃. At first the name *left ventricular hypertrophy* was given. When it was realized that a deep S₃ was not always associated with hypertrophy of the left ventricle, the name *left ventricular preponderance*, and when the inaccuracy of the latter became evident, the present name—*left axis deviation*—came into use. It has been shown that a large Q₃ may be found with normal

FIG 7 A case of aneurysmal dilatation of an acute myomalacia. Note the Q₁ T₁ type of ventriculogram. Note also the inverted P₂. Taken 14 days after occlusion.

adult hearts, with infants' hearts, in pregnancy, and with coronary artery disease. We believe that the common factor represented is a rotation of the electrical axis about its longitudinal axis—in some cases produced by extra cardiac causes and in some cases produced by changes intrinsic in the ventricle. Other electrocardiographic changes and clinical findings must be sought as clues to the causation of any particular Q . (The same applies to Q_1 .)

SUMMARY AND CONCLUSIONS

1 In normal ventriculograms Q_1 , Q_2 and Q_3 correspond in time with reasonable accuracy. In normal ventriculograms, therefore, the term " Q " represents a physiological entity and determination of its significance can be attempted.

2 In ventriculograms of the large Q_3 type, Q_3 does *not* correspond in time with Q_1 or Q_2 . The time represented by Q_3 in 50 of these tracings was in *no* case identical with that occupied by Q_1 and Q_2 . In *most* of these tracings part of Q_3 corresponded in time with parts of R_1 and R_2 . In *many* of these tracings Q_2 corresponded more or less accurately in time with R_1 or R_2 .

3 Evidence was offered to show that a large Q_1 is usually associated with characteristic changes in R and S—suggesting an alteration in the ventricle as a whole, rather than in one part of it in these cases.

4 It was suggested that a large Q might be indicative of a rotation of the ventricular electrical axis around a longitudinal axis, rotation to the left producing a large Q_1 , and rotation to the right a large Q_3 .

5 Such rotation could be the result (a) of mechanical factors changing the position of the ventricle, (b) of a change in the position of the leads, causing a relative rotation of the heart, (c) of damage to one part of the ventricular musculature with collapse, the contraction of scar tissue, or dilatation of the damaged area, (d) thickening of one part of the ventricular musculature.

6 In a particular electrocardiogram there is no more reason for considering a large Q_3 indicative of coronary artery or myocardial disease than there is for regarding a deep S_3 as indicative of hypertrophy of the left ventricle. We believe that a large Q_3 , like a deep S_3 , is caused by a change in the relative position of ventricular musculature—for which many different causes may be responsible.

CERTAIN BASES OF PHYSICAL THERAPY *

By THOMAS P. SPRUNT, M.D., F.A.C.P., *Baltimore, Maryland*

DURING the past year it has fallen to my lot to become particularly interested in physical therapy. What I shall have to say is addressed not to expert physical therapists but to practicing physicians who, like myself, have had heretofore but a desultory interest in the subject and while not deeming the value of empiricism in therapeutic methods, would still wish to know something of the underlying physiological factors that may have been determined.

Although physical therapy may have been over-exploited here and there during the past several years, one gets the impression that it is much more widely neglected to the great detriment of many patients who are badly in need of it. The Council on Physical Therapy of the American Medical Association is doing a valuable work in disseminating useful information on this subject and in protecting the profession against misleading and deceptive advertising. They have wisely emphasized the point that among the physical methods of treatment the fundamentals are massage, active and passive exercise, muscle training exercises and the application of heat. As a corollary to this statement one may add that a well trained, skilful technician, intelligently directed, is of more value than much costly apparatus.

In addition to manual methods, what external stimuli do we find employed? Perhaps it will serve a unifying purpose to glance for a moment at the range of electromagnetic rays, the source of so many marvels in the physical world of today. On the left of the range are the shortest waves, the so-called cosmic rays, then successively with increasing wave lengths, the gamma rays, the x-rays, and after a relatively unknown gap the ultra-violet or chemical rays, the narrow band of visible light (from 360 to 760 millimikrons), followed by the broad band of infra-red or heat rays, the Hertzian rays that include the shorter and the longer radio waves, and finally at the extreme right of the range, the alternating current waves. You will note that many of our physical therapy modalities have their bases in electro-magnetic rays of one or another wave length, and it is safe to say that the potentialities of further discoveries in this electro-magnetic range seem infinite.

In the use of physical methods one may wish to affect many different tissues and parts of the body, but the most exposed and the most accessible of them all is the skin with its immediately subjacent tissues. We have all been taught, but we are prone to forget, that the skin is not merely an integument, a covering for the body, but a complex tissue with many func-

* Read at the Chicago meeting of the American College of Physicians, April 18, 1934

tions Let us pass some of them in review First, there is the integument, a physical barrier to the outside world Second, the sebaceous glands Third, the blood vessels with their remarkable reactions in maintaining and regulating body temperature and in defense against injury Fourth, the lymph vessels Fifth, the sweat glands with their service in temperature regulation and in excretion Sixth, the function of insensible perspiration, also of value in temperature regulation Seventh, the nerves and nerve endings, the sources of sensory impressions and of reflex activities Eighth, other metabolic or chemical factors under which we may mention (a) resorption, a factor of little importance in the human skin, (b) pigment formation, (c) the histamine-like substance postulated by Lewis, (d) ergosterol, which is changed by ultra-violet irradiation to viosterol, with the production of vitamin D, (e) the high potential of tissue immunity emphasized by Kahn who finds that the skin possesses a specific reacting capacity for antigens more than ten times as great as the reaction capacities of muscle, of brain, or of plasma

The skin then is a complex structure capable of a variety of reactions to stimuli both from without and from within The vascular mechanisms are particularly intriguing and have been studied by many physiologists, including Sir Thomas Lewis, who found that numerous and widely different forms of stimulation yield in common three distinct events, these are (a) a primary and local dilatation of the minute vessels of the skin, (b) a widespread dilatation of the neighboring strong arterioles brought about entirely through a local nervous reflex, and (c) locally increased permeability of the vessel wall In explanation of this complex mechanism he postulates the release of a histamine-like substance and considers it a normal metabolite that is responsible for many of the normal vascular reactions as well as those occurring under conditions of stress In the light of such researches it seems entirely probable that many of the reactions of the skin and other tissues to physical therapeutic procedures are really defense reactions on the part of tissues to outside agencies and are non-specific as far as the particular therapeutic method is concerned There are of course specific responses as illustrated by the difference in the skin reactions to heat rays and to ultra-violet rays, and by the striking difference in reflex activities following the applications of cold and of heat All these responses, specific and non-specific, may be considered defense mechanisms and whenever the defense reaction is favorable to the condition under treatment, the therapeutic method is useful

HEAT

As many of the procedures in physical therapy involve the use of heat, we may well consider next some of the results of local and of general heat that have been determined by physiological experiments Let us recall that although we customarily speak of the body temperature as 37°C (98.6°

F), the temperatures in different parts of the body are not the same. There are many temperature gradients that may be modified by the application of additional heat.

The heat capacity of the tissues is high (0.8) so that considerable heat may be absorbed before a change in temperature can be measured. This capacity varies also with different tissues. The conductivity of heat in the tissues is made quite variable by the marked changes in vascularity. When the skin and subcutaneous fatty tissues are cold and the vessels contracted, the conductivity is relatively poor and less heat is given off from the surface. When, on the other hand, the tissues are warm and the vascular channels dilated, the conductivity is markedly increased.

Heat may, of course, be applied by different methods, namely, by conduction as with the hot bath or a hot water bottle, by convection as from hot air, by radiation as from the sun or therapeutic lamps, and by conversion whereby electrical energy is converted into heat within the tissues of the body as by diathermy. A favorite method for superficial heating is the use of radiant energy, the most valuable wave lengths for this purpose being those of visible light and of the infra-red. The wave length with the greatest penetrating power through the tissues is given as 1150 millimikrons, that lies in the near infra-red. This wave length is best obtained by the use of a gas filled, tungsten filament bulb.

Owing to the slow penetration of heat by conduction when it is applied to the surface, to the relatively poor penetration of the infra-red rays, and to the efficiency of the local vascular protective mechanism, it is now generally believed that the use of diathermy is the method of choice in attempting to heat the deeper tissues in most conditions where this is desired. Even here, although the heat is generated within the tissues themselves, it is rapidly dissipated, no great storage of heat occurs and there is no striking rise of temperature. But after all, the chief purpose in the local use of heat in physical therapy is usually not so much the production of an increase in temperature per se as an acceleration of the circulation, an increase in blood flow, which must occur in a part where there is a large additional amount of heat to be dissipated. Hence the absence of any striking rise in temperature is not necessarily an indication that a useful purpose is not served by the treatment.

In view of the importance of an active circulation for the dissipation of heat within the tissues and for their protection from damaging degrees of heat, one must needs be careful in its application to parts where the local circulation is notably defective. Here we have an explanation of the well founded dread of heat that many physicians have in the treatment of gangrene and even of the lesser manifestations of peripheral vascular disease. This danger would seem to be obviated by the method of controlled heat suggested by STARR, who finds that the optimal temperature in such cases is usually that of the normal skin temperature of the part.

The Effect of Heat on the Circulation This very important effect of heat is exerted both directly upon the vessel walls and reflexly through the vasomotor nerves. Heat produces vasodilatation and cold, vasoconstriction. Not only is the effect a local one but through the reflex activities distant parts of the vascular tree may be affected as has been demonstrated definitely by Lewis and others.

There are marked variations in the blood flow as the result of heat or of cold. The local circulatory rate in the arm in an arm bath has been measured and recorded. At 32°C (approximately the normal temperature) the flow of blood was 13 cc per 100 cc of tissue per minute. At 26°C the flow was 5.5 cc of blood per 100 cc of tissue per minute. At 46°C the flow was 26 cc of blood per 100 cc of tissue per minute.

Heat also produces a marked increase in the transudation of fluid from the blood vessels and hence in the formation of lymph. When these vascular changes are widespread as in a warm bath, for example, there occur definite readjustments in the fluid balance with increased formation of lymph in the skin and subcutaneous tissues but, in the splanchnic area vasoconstriction, diminished capillary tension and increased absorption of water. Similarly, cold applications to the skin may result in vasodilatation of internal vascular beds and a consequent diuresis.

Effects of Heat on the Blood When the blood is heated locally there are marked changes in its physical chemistry with a shift toward the acid side as is illustrated in the following experimental record. The blood was obtained from an arm vein after the arm had been placed in a water bath at the different temperatures. At 33°C (91.4°F), pH 7.45, pOH 6.3, CO_2 tension 35 mm, O_2 saturation 70 to 90 per cent, O_2 tension 45 to 55 mm. At 40°C (104°F) pH 7.3 to 7.4, pOH 6.2, CO_2 tension 45 mm, O_2 saturation 90 per cent +, O_2 tension 70 to 95 mm.

The Effect of Heat on Metabolism The metabolism of the tissues is definitely increased by heat. As tested upon an isolated organ, as in the perfused heart, it is estimated that the metabolism increases two or three times with a rise of 10°C .

There is an interesting experiment in the study of cyanosis in the forearm produced by stasis due to a constricting band on the upper arm. In a water bath at 31°C (87.8°F) cyanosis was obvious in three minutes, at 42°C (107.6°F) cyanosis occurred in one minute, at 15°C (59°F) no cyanosis occurred in 15 minutes. From this experiment it is obvious that the usage of oxygen was markedly affected by the changes in temperature.

Hitherto we have been dealing with the local application of heat. As you well know, by more general heat applications or by the prevention of heat loss, a rise in the general body temperature can be induced. The complex changes that are brought about by elevating the body temperature may be summarized as follows. Increased circulatory rate, rise in blood volume, marked increase in the ventilation rate, fall in alveolar CO_2 tension,

rise in oxygen consumption, increased metabolism, and changes in the pH of the blood and urine to the alkaline side. Clinical work indicates a definite change of tone in the autonomic nervous system.

EXERCISE

To quote Bair: "Muscular exercise is accompanied by the coordination and integration of many functions. The participation of higher nerve centers, and the increased respiration and circulation are as much a part of exertion as the muscular contraction itself." During the contractile phase of muscular activity there is a breaking down of glycogen into lactic acid and during the recovery phase the lactic acid is re-converted into glycogen. "Due to the accumulation of acids there is during the contractile phase a diminution of alkalinity, not only in the muscles but also in the whole body, a change which is corrected during the recovery phase."

MASSAGE

With massage, on the other hand, there are no such complicated readjustments as in active exercise, nor do we find metabolic changes like those associated with the use of heat. There does occur, even with light stroking, a non-specific reaction on the part of the minute vessels of the skin, and with deep massage doubtless of those in the muscles also. Capillary dilatation has been observed microscopically by Pemberton and others following light massage. There is further the mechanical assistance to the venous blood flow and also the lymph flow with presumably in this way an aid in the removal of waste products from the tissues affected. Probably in this way, too, is brought about the increase in the red blood cells and hemoglobin of the circulating blood as well as the increased oxygen capacity that has been noted following massage. In spite of the paucity of physiological data there is no doubt from the empirical standpoint of the value of massage. One of the most ancient, it is also one of the most valuable measures in the realm of physical therapy. Of great value to many chronic invalids who must, for one reason or another, remain in bed for periods of weeks, it is really indispensable in the rehabilitation phase of the treatment of injuries and of many diseases of the bones, joints and muscles. Yet so great is the neglect of this useful procedure in many localities that patients must go to the osteopath or to the chiropractor in order to receive its benefits.

THE ULTRA-VIOLET RAY

The treatment of rickets, infantile tetany and osteomalacia by means of the ultra-violet ray rests upon abundant biochemical studies. It is generally agreed that the favorable effects are due to photochemical reactions resulting from absorption of the rays and the prevailing opinion at present favors the view that the sterol in the skin is rendered photoactive by radia-

tion It has been shown that irradiated animal or human skin is antirachitic and that this action is independent of the nervous or circulatory systems

The use of ultra-violet rays or of heliotherapy in the treatment of extrapulmonary forms of tuberculosis, of erysipelas, and other superficial infections rests chiefly upon an empirical basis

In conclusion, in this brief and quite incomplete discussion of certain bases of physical therapy it is suggested that they are chiefly defense mechanisms of the tissues in response to external stimuli and that the most valuable of these mechanisms from the therapeutic standpoint would seem to be those of the vascular system with increased flow of blood through the part treated

THE DIABETIC CHILD

ETIOLOGIC FACTORS

By HENRY J. JOHN, M.D., F.A.C.P., *Cleveland, Ohio*

HEREDITY

Heredity is the most important factor in the causation of diabetes in children. In a study of literature from all over the world, which includes 1,418 cases of diabetes in children, the disease was hereditary in 30.8 per cent (table 1). In reality this percentage is higher, for the longer the

diabetic children live the more diabetes is discovered in their families. The true percentage on this basis is probably somewhere near 40 per cent.

In my own series of 214 cases of diabetes in children and adolescents, the proportion in which heredity played a part was about equal in the boys and the girls, namely 18.7 per cent (table 2). There was an interesting contrast, however, in the hereditary factor among Gentile and Jewish children. In the Gentile children, there was a family history of diabetes in 17.9 per cent, whereas in the Jewish children it amounted to 30 per cent (table 2). Unfortunately I have no figures to offer for the incidence of childhood diabetes in the two races.

P. White in a series of 533 diabetic children, 45 of whom were Jewish, found the hereditary incidence to be 44 per cent in the Jewish group, and Priesel and Wagner in Vienna, in a series of 108 children, 29 of whom were Jewish, found 43 per cent with a familial history among the Jews, as contrasted with 21 per cent in the Gentile group (table 3).

It has been pointed out by many authors that diabetes is transmitted as a recessive character according to the Mendelian law. This is shown graphically in figure 1, in which the black dots represent the diabetics, the clear rings the non-diabetics, and the half clear rings the non-diabetics with a hereditary background. The first diagram shows that when a diabetic marries a diabetic all the children will be diabetic, the second that in a union of a diabetic with a nondiabetic with a hereditary background, one-half of the children will be diabetic. The third diagram shows that when a nondiabetic with a hereditary background marries a nondiabetic of the same type, one-fourth of the children will be diabetic, and the fourth shows that when a diabetic marries a normal person with no familial background of diabetes, no children will be diabetic.

This then gives one a practical working basis for prognosis and indicates the practical and moral responsibility which we physicians face in advising a diabetic concerning marriage. If the birth of future diabetics

FIG 1 Heredity in diabetes Illustration of the Mendelian recessive

FIG 2 Twins with diabetes The sex, the interval of time between the onset in each pair and the author who reported them

is to be prevented the other partner must not only be nondiabetic, but also have a family history free from diabetes

Figure 2 presents a study of diabetic twins arranged according to the time interval between the onset of diabetes in each pair in a total of 19 pairs of twins reported in the literature. In three pairs the onset was simultaneous, and in four pairs within 12 weeks of each other. Such data present instructive and presumptive evidence of the hereditary nature of diabetes.

INFLCTION

Infections play a considerable part in the production of diabetes in children. When one considers the havoc which an infection plays even in a mild case of diabetes, one can readily understand why an infection might precipitate diabetes in a diabetotrophic child, that is, one with a tendency toward diabetes. Figure 3 illustrates the damage caused by infection in

FIG 3 Infection and the part it plays in a child who was a mild diabetic Note the permanent loss of previous tolerance

the case of a little boy, aged four years, whose diabetes had improved under adequate treatment so that all insulin could be discontinued. He presented a normal fasting, noon and evening blood sugar and was sugar-free on diet alone on repeated examinations. He contracted measles and, as the physician who was attending him in the small town where he lived did not appreciate the change in the situation and the need for reinstating insulin during the course of the infection, when I saw him a few weeks later his blood sugar was almost 500 mg per cent and he displayed signs of severe

acidosis Insulin had to be reinstated in large quantities and to this day he is taking large quantities of insulin, because the faulty management during the infection wrought permanent damage which apparently is irreversible This case shows the importance of proper management during acute infection in a diabetic child

There is some evidence that in all acute infections, even in normal persons, there is decreased sugar tolerance If the reserve insulogenic function is sufficient, it is not exhausted even by repeated infections But a lesser reserve is more easily exhausted and diabetes may be thus precipitated Unfortunately we usually see these children at the time when diabetes develops and we know little or nothing of their background, that is, whether that child had diminished insulogenic function before the infection or whether this was normal This phase of the problem of diabetes will have to be explored if we expect to arrive at any sort of logical solution, which will aid in the prevention of diabetes Prevention, after all, is the only worthwhile goal, for we cannot cure diabetes, but with increased knowledge we should be able to reduce its incidence

That infection does play a part in the development of diabetes in children can be deduced from figure 4 These data on a group of my own series

FIG 4 The onset of diabetes in a group of 34 children from my own series following the various infections and the length of time intervening between the infection and the onset of diabetes

of cases show the relation of the onset of diabetes to preceding infection. The time between the infection and the onset of diabetes often is very short, in some instances only two days, in nine cases 10 days and in 15 cases 20 days. Such evidence can not be disregarded. In table 4 I have gathered

TABLE IV
Onset of Diabetes in Children Following Infections

| | Number of days after infection when diabetes was discovered | | | | | | Not Stated | Total |

from the literature cases of diabetes in children following an infection and have added similar cases from my own series. I do not know the background of these children, that is, whether they were perfectly normal or whether they were children with a diabetic tendency, a diminished insulogenic function, the "Minderwertigkeit" of the Germans. I suspect the latter, but I cannot be sure. Priscilla White¹ in her book on "Diabetes in Children and Adolescence" states that "infections play no rôle or are of little or no significance in the production of diabetes in children." This statement certainly is contrary to my own experience.

A. Jones² in England called attention to the fact that following an influenza epidemic, the incidence of diabetes increased. Lierle and Potter³ of Iowa City, in their study of the diabetic child, state "we have observed that low grade and early diabetic conditions are recognized first during acute colds and tonsillitis." Von Noorden⁴ also believes that diabetes does develop following infection. Hirschfeld⁵ has expressed the view that an infection such as angina or flu causes damage to the pancreas and can bring about diabetes. Freise and Jahr⁶ state that nearly three-fourths of their diabetic children developed diabetes shortly after acute infections. Similar statements have been made by von Starck,⁷ Weiland,⁸ et cetera.

Pancreatitis follows at times as a complication of parotitis. It is perhaps more frequent than the literature would indicate, for not all cases are reported. In 1900, Jacob⁹ reported a case in a child, aged 10 years. In that same year Priestley¹⁰ reported two cases, one in a boy aged 14 and the other in a man of 25. Auché¹¹ in 1905 reported two cases in boys 9 and 12 years of age. Biahdy and Scheffel,¹² Gentry,¹³ Stevens¹⁶ and others have reported additional cases. Farnam¹⁴ collected from the literature 119 cases of pancreatitis complicating mumps and added one of her own. Barbieri¹⁷ tells of a boy six years old with mumps during an epidemic. Six days after the onset of the symptoms he complained of a continuous pain above the umbilicus which radiated around the right side to the right lumbar region. The pain continued, next day he vomited and developed diarrhea. Two days later he had a voracious appetite and a great thirst but everything he ate he vomited an hour later. He drank two liters of water a day. The urine was loaded with sugar. The symptoms subsided gradually and disappeared after 15 days and by that time the urine was sugar-free.

That infection produces a marked rise of blood sugar even in young infants, or produces a diabetic type of curve was shown by Fritz Goetzky¹⁷. In an infant three and a half months old with fever and bilateral bronchopneumonia, the fasting blood sugar was 79, but after the administration of 10 gm of glucose in tea, the blood sugar taken after three hours was still 264 mg per cent. In another infant, two months old, with fever and hydration, the fasting blood sugar was 120 when the fever subsided on the third day, but when 12 gm of glucose were given in tea the blood sugar rose to 178 at the end of the second hour and at the end of the fourth hour it was still 134. Lauritzen¹⁸ recommended as a prophylactic step in diabetes the testing of children's tolerance by the production of glycosuria *et amylo*.

MacLean and Sullivan¹⁹ studied the tolerance of 97 children from three months to five years of age with various diseases. Seventeen infants with infections in the acute stage did not reveal any consistent change in the carbohydrate metabolism. Ten showed normal, six increased, one decreased tolerance.

This I think is quite suggestive. Out of the 17 children but one showed a decreased tolerance. Why? Was the infection due to a more toxic organism or was the infant one with a smaller insulogenic reserve? This is the type of child to follow carefully through succeeding years, for if the decreased sugar tolerance was the result of lessened insulogenic reserve this child should later in life develop diabetes. This sort of study forms the foundation on which we can build and eventually hope to reach the point of better understanding of the functional background of diabetes. It may lead nowhere and again it may shed much light on this problem.

According to Williams and Dick²⁰ there is a lowering of dextrose tolerance in acute infections and it may last for several months.

Labbe and Boulin¹ stress the fact that during infection glycemia is increased and the glycemie curve is four times longer, with the maximum hyperglycemia increased by 50 per cent. This reveals an important change of the sugar regulating balance. Alimentary glycosuria was noted in 75 per cent of their series. The disturbance of the glucose regulation did not parallel the gravity of the infection. The impairment of glucose balance sometimes becomes more pronounced during convalescence and persists for weeks or even months after recovery from the infection. There was no sign of an insufficient functioning of the liver. "It is possible," they say, "that recurrences of this transient disturbance of glucose balance creates a true diabetes more frequently than hitherto believed."

As an explanation for the hyperglycemia during infection, five possibilities present themselves: (1) reduced insulin output, (2) inability of the liver and the muscles to store glycogen readily, (3) the action of insulin may be interfered with as it is in acidosis and fevers, (4) the nervous control mechanism may not be functioning properly, and (5) there may be an increased output of adrenalin which increases the hyperglycemia. Goetzky¹⁷ and Czeiny think that the second factor is of prime importance. Hahn,²² Offenbacher²³ and John²⁴ think number one is the most probable factor. Various authors have expressed the opinion that the third factor is of major significance. All five may be important and at different times the various factors may be involved in various proportions.

Root and Warren²⁵ state "The character of the lesions of the islands of Langerhans suggests a toxic origin acting over a long period of time."

I have always felt that if liver damage were of prime importance hyperglycemia would be encountered more frequently, furthermore, in patients with marked cirrhosis of the liver, there is no hyperglycemia. Waikany²⁶ studied the level of fasting blood sugar in a three and a half year old child with cirrhosis of the liver. The fasting blood sugars were normal, 60-106. A glucose tolerance test, using 30 gm of glucose, produced a normal curve.

Were the insulogenic function involved, the hyperglycemia should be in direct proportion to the insulogenic reserve of the individual. Even here one will not get a clear picture as the problem is a complex one for there can be a marked insulogenic derangement of a temporary nature, which, once relieved, will quickly return to good function, and if not relieved and if prolonged it may go on to a frank diabetic state. That this occurs I²⁴ have shown in previous publications.

In figure 5 are shown the blood sugar changes during and after pneumonia in a child three years old. I have constructed these curves from Kohn and Felshin's²⁶ figures. Note the marked rise and slow fall of blood sugar during the crisis and the subsequent drop of the curve after the infection has subsided. In the first curve starvation tends to distort the curve toward the diabetic side. In diabetics during an infection the

insulin requirement is greater and we speak of this as inactivation of insulin. There is also an increased adrenalin output during infection. We might well be dealing with a similar problem in regard to the endogenous insulin in such a case of pneumonia. The important thing is that in most cases the decreased glucose tolerance is but temporary, but occasionally it

FIG 5 Glucose tolerance tests in a three year old infant with pneumonia at crisis, four days after crisis and eight days after crisis

becomes permanent which means that the patient has diabetes. Are these exceptions due to a less efficient insulogenic function with which the child started life? Or is it a certain type of action of bacteria and their toxins on the pancreas? I have no answer to offer.

I have followed out this problem a bit further in a comparative study of glucose tolerance tests on children and adults with various affections

The findings were quite striking (Figure 6) In obesity and hyperthyroidism, for instance, adults show diabetic curves about three times as often as do children In glycosuria, rheumatism and hypopituitarism the incidence is about the same In hypopituitary disease there is an increased sugar tolerance Sixty-six per cent of cases of glycosuria are nondiabetic Rheumatic conditions and chronic infections carry a heavy

FIG 6 Comparative studies of glucose tolerance tests in adults and children afflicted with the same condition

incidence of diabetic curves both in children and adults Hyperthyroidism does not disturb the carbohydrate tolerance of the child nearly so much as it does that of the adult, the same can be stated regarding obesity Here then we have the difference, functional I think, between the child and the adult The child is a better physiological unit on the whole than the adult who has been harassed by infections, wear and tear, dietary abuses et

eetia for decades and has thus exhausted much of his reserve. Any superposed strain on such a background produces a different picture from that where the background is intact.

OBESITY

A series of 1306 cases of adiposity was reported in 1925 by Anders and Jameson.²⁷ In this series the authors found 119 or 9.1 per cent of the patients had diabetes. The general incidence of diabetes is at most 2 per cent so that the increase in the incidence of diabetes as judged from this series is about 500 per cent. In my series of diabetics, 76 per cent of the patients were more than 10 per cent overweight at some time during their lives. The threat of diabetes, then, is very real to the adult who is obese.

The question of obesity in children fortunately does not present such a serious outlook, but Mouriquand²⁸ in 1920 warned us to be on the alert to detect incipient obesity in children of the obese, the diabetic, the arthritic and the gouty parents. He says that nearly all of his patients who had early inherited obesity developed diabetes before the age of 40, but that when the inherited obesity did not develop until later in life only 50 per cent became diabetic, and in acquired obesity only 15 per cent developed diabetes.

In my glucose tolerance studies on obese children and adults it was shown that the children had three times the resistance to diabetes that the adults had. This is well illustrated in the case reported in 1925 by McKinley²⁹ of a girl 18 years of age who had endogenous obesity and weighed 346 pounds. Her blood sugar and glucose tolerance test were normal. On the other hand Wagner³⁰ reported the case of an obese girl, 12 years of age, who was diabetic in the presence of definite hypothyroidism which usually is accompanied by an increased tolerance. Lindblom³¹ reports a boy, 16 years old, with hypothyroidism and severe diabetes who died in coma.

However, on the whole, the problem of obesity in children plays but a minor rôle as can be gleaned from figure 7, which shows the incidence of obesity in the various decades in a series of 528 of my cases which I analyzed some time previously. In the first decade it amounts to but 1 per cent, though the second decade already shows an increase.

Nevertheless, one should look upon an obese child with suspicion and settle the problem regarding its carbohydrate metabolism. The treatment of obesity in children depends upon the underlying cause for it, which often is of endocrine origin.

ARTERIOSCLEROSIS

While arteriosclerosis frequently accompanies diabetes in the older patient and probably plays an important part as an etiologic factor, it is almost a negligible factor in the young. Pearl Zeek,³² who searched the literature over the last 100 years, found but 98 cases of juvenile arteriosclerosis.

FIG 7 The incidence of overweight in 528 diabetes from my own series in the various decades

excluding those due to luetic infections and, as far as could be determined, none had diabetes. Nephritis, lues, and tuberculosis are factors which are most frequently associated with premature arteriosclerosis. Arteriosclerosis, however, does appear in the diabetic child after he has had diabetes for a number of years much more frequently than it does in the nondiabetic child.

HYPERTHYROIDISM

That hyperthyroidism in children is not a rarity is a well known fact. In table 5 I have gathered 285 cases reported in the literature.

In a study of 9,000 hyperthyroid adults³³ I found 6.88 per cent with a derangement of carbohydrate metabolism which manifested itself by a nonphysiological hyperglycemia either with or without glycosuria. This derangement during the acute stage of hyperthyroidism often is considerable. Thus in a series of 239 glucose tolerance tests on adult patients with hyperthyroidism, 64 per cent gave a curve like that of diabetes. I have considered this as a lack of physiological response. Either the glycogen storage function is at fault, or the nervous control mechanism which regulates the insulin output is interfered with, or else there is an abnormal

TABLE V
TOXIC GOITER in Children

stimulation of the adrenals producing hyperglycemia, or a temporarily lessened insulogenic function, or the insulin does not act properly as is the case during infections. Any one or all of these factors are possibly of importance but which one predominates and to what extent we do not know.

In a series of 9,000 cases of hyperthyroidism I analyzed 620 cases of glycosuria carefully. During the derangement of the carbohydrate metabolism these patients were closely watched and received adequate insulin for their protection, but not all of them regained their normal insulogenic function. One hundred and eighty-six patients remained diabetic and receive treatment for diabetes to this date. Thus the actual incidence of diabetes in hyperthyroidism in my series was 21 per cent with protection. What it would have been without such protection I do not know, but I venture to say that it would have been considerably higher. But even so it is about 100 per cent more than the general incidence of diabetes.

When we come to study the problem of hyperthyroidism in the child we see a different picture. Figure 6 shows that diabetic curves occur in cases of juvenile hyperthyroidism only about one-fourth as frequently as they do in the hyperthyroidism in adults. Apparently the greater reserve or flexibility in the young can withstand a grave metabolic derangement and still right itself. In my own series of children with hyperthyroidism who were protected during and after the acute stage of hyperthyroidism none developed a frank and lasting diabetes. This is in sharp contrast with the adult group. I have under my care, however, two children with diabetes who had some derangement of their carbohydrate metabolism during the acute stage of hyperthyroidism. Both were subjected to thyroidectomy. Both were told by the surgeon to forget about their blood sugar and both returned later with frank diabetes and are under treatment.

to this date Had these children been protected for six months or a year, they might not be diabetic today

On the whole, hyperthyroidism plays but an insignificant part as an etiologic factor in the production of diabetes in children When abnormalities in the carbohydrate metabolism are found, they should be controlled thoroughly by a liberal diet and a sufficient amount of insulin to insure proper utilization of the food Sugar free urine together with normal blood sugar should be attained and maintained long after operation until a complete restoration of function has taken place Only thus can diabetes from this source be prevented

LULS

All authors are agreed that luetic infections are of no significance as an etiologic factor in diabetes Joslin and the European authors express themselves alike in this respect and in my own series I found none in whom syphilis could have been a predisposing factor Lasalle¹ studied a group of four diabetic infants from poor families and he stated that syphilis was a probable cause of the diabetic condition While lues does play a small part in the production of diabetes in adults or at least accompanies it, in children it is a negligible factor

SUMMARY

1 The average percentage of cases of diabetes in children in which heredity was an etiologic factor in a series of 1,413 cases from the literature was 30.8 per cent In my series of 214 cases of diabetes in children the hereditary incidence was 18.7 per cent In Jewish children there was a hereditary influence in 39 per cent as contrasted with 19.4 per cent in Gentile children In my own series, the incidence in Jewish children was 30 per cent and 17.9 per cent in the Gentile group Diabetes apparently is a recessive character according to the hereditary laws of Mendel Heredity in 19 pairs of twins is analyzed according to the time interval between the onset of diabetes in each pair In three pairs it was simultaneous

2 Infection in diabetic children requires close and adequate management if the child is to emerge from it without further impairment of sugar tolerance In my own series of diabetic children, in nine cases, or 4.2 per cent, the onset of diabetes followed within 10 days after the infection, in six cases, or 2.8 per cent, the onset was within 20 days, in 45 cases, or 21 per cent, the onset was within 60 days The onset of diabetes may follow any acute infection and every child should have a weekly urine examination until there is ample evidence that sugar is being utilized normally In the early stages of diabetes, the process is to a certain extent still a reversible one whereas at a later stage no repair is possible

3 Comparative studies of glucose tolerance tests in children and in adults having various affections present a striking and an interesting con-

trast between the two groups in obesity and hyperthyroidism. In rheumatism and glycosuria and hypopituitarism they are practically alike.

4 Obesity in the adult presents a high incidence of diabetes, as much as five times the general incidence of the disease. Obesity in children does not present a major etiologic problem.

5 Arteriosclerosis is not a causative factor of juvenile diabetes.

6 Hyperthyroidism plays an insignificant rôle as a causative factor in diabetes in children as contrasted with the same condition in adults. However, nonphysiological hyperglycemia during active hyperthyroidism should not be disregarded and the child should be given protection during this period until the carbohydrate metabolism has returned to its normal function.

7 Lues can be disregarded as a causative factor of diabetes in children.

PSYCHOLOGICAL CONSIDERATIONS IN THE TREATMENT OF THE NEUROSES *

By ARTHUR H. JACKSON, M.D., *Washington, Connecticut*

THERE can be little question but that a very large proportion of those who consult their physicians for other than purely surgical, acute infectious or obstetrical conditions are suffering from some form of neurosis, which, in many cases, is psychogenic in origin. The *function* of some organ or organs is at fault while the organ itself is in no way diseased. The diagnosis of such a condition as some form of organic disease is one of the commonest errors in diagnosis met with today. The battle-scarred abdominal wall of one who has submitted to one surgical procedure after another in seeking a cure is altogether too commonly seen, nor is it surprising that this should be the case. Ever since the beginnings of scientific medicine in the seventeenth century, and particularly during the last hundred years, the main emphasis in medical education and practice has been on the physical side of man and but little attention has been given to the mental. Most of those who are now practicing medicine were well trained in anatomy, physiology, biological chemistry, pathology and bacteriology but comparatively few received any instruction to speak of in psychology. In the clinical field, too, almost the entire emphasis up until a few years ago was placed on organic disease, and many medical schools have offered courses in clinical psychiatry for the first time during the past half a dozen years. What wonder, therefore, that physicians so largely seek to find a physical basis for all disease states and fail to consider a possible disorder of the psyche. Sir William Osler counseled us always to bear syphilis in mind when making a diagnosis but it is even more true of a neurosis that it can masquerade in the guise of almost any organic disease. To mistake a neurosis for organic disease has the most serious consequences for the patient, as the major surgical or prolonged medical treatment of a neurotic is much more harmful in its consequences for him than for the emotionally stable individual. To differentiate between a functional and an organic condition is often a major test of the diagnostic acumen of the physician.

But when the diagnosis of a neurosis has been made, how should the individual be treated? Plato said, "As you ought not to attempt to cure the eyes without the head or the head without the body, so neither ought you to attempt to cure the body without the mind and this is the reason why the cure of many diseases is unknown to the physicians of Hellas, because they are ignorant of the whole, which ought to be studied also." The individual must be studied as a whole, both body and mind, in order to determine

* Received for publication March 20 1934

From the Department of Internal Medicine, Yale University School of Medicine

the genesis of his neurotic symptoms. A careful search must be made to find out what, if any, organic disease is present, but the patient's personality must be studied also.

Often a very superficial knowledge of the patient is sufficient, and simple suggestions for rest, a change of scene, slight dietary modifications and sedatives may work wonders. But in other cases, much deeper studies of the patient may be necessary. Herbert Spencer said, "Life is a series of internal adjustments to external environment" and the neurotic person is often one who fails to make the adjustments satisfactorily with resultant deep emotional disturbances which are hard to discover. The emotions are the source of a large part of man's psychic energy when his emotional life runs smoothly. But when it fails to do this and major emotional conflicts develop, the individual is apt to suffer from a neurosis. It may, therefore, be of the utmost importance to understand the emotional make-up of a patient and the way in which he reacts to his particular problems of life. This may entail a detailed survey of the patient's early education and environment, his likes and dislikes, his hopes and fears, his degree of introversion and extroversion, his sexual adjustment and other emotional reactions. One is apt to hear the remark "O! He's just a neurotic" as if a neurotic were an inferior being. This is often far from being the case and the patient is simply emotionally immature rather than inherently inferior. To discover the deep lying emotional factors in a case and then to re-educate the individual to meet his particular problems in life without the development of neurotic symptoms is both the problem and the method of successful approach for the physician. A broad understanding of human nature and some knowledge of so-called "mental mechanisms" is of the greatest help to the physician in accomplishing these aims.

The following cases are reported to show (1) how a neurosis may simulate organic disease, (2) that the causes of neuroses are often psychological, and (3) that the symptoms usually disappear if the patient's emotional conflicts can be solved. None of these patients had any organic disease which was in any way related to their neurotic disorder.

CASE I

The patient complained of intense nervousness and hoarseness. He was in a highly agitated state, could eat and sleep but little and spoke in a hoarse whisper. He had been sued for misuse of funds that had been entrusted to his care and, when called to the stand to testify in his defense, he suddenly lost his voice. The judge granted a postponement so that he could recover his voice and not have to testify under a disadvantage. The man had been receiving local treatments for his aphonia without any benefit and had finally been told that he must stand trial in spite of his physical condition. He felt confident that he could vindicate himself, and his lawyer assured him that he had nothing to worry about. But there were many things about this man's personal life which no one knew about except his opponent and he was afraid that they would come out at his trial. He was no physical coward. Powerfully built, mentally alert he had stroked his university crew and had seen four years of active service at the front during the World War as a captain in the British army. He

had been decorated more than once for bravery under fire but he could not face the possibility of losing his case in court and, with it, his reputation as an honest and highly moral man. He was told that he would not recover the use of his voice until he went through with his trial. The case was tried. The patient testified and promptly recovered his voice and usual calmness even though he was convicted.

This is a typical case of hysterical aphonia which failed to respond to local medical treatment and disappeared only when the emotional conflict which produced it was resolved. Like many of the cases of "shell shock" in the World War, the patient unconsciously developed a symptom which protected him from facing a situation of which he was afraid.

CASE II

A white woman of 33 complained of repeated convulsive seizures over a period of nine months and severe backache over a period of 10 years. She had been under various physicians' care at different times for her backache and had received but little help. Finally, 18 months before she came under observation, a suspension was done in the hope that the backache would be cured when her retroverted uterus was put in good position. The objective of the operation was attained but the backache continued. After a slow convalescence of nine months the patient was about to return to her work when she had her first convulsive seizure. Although thorough examinations of many kinds were made, no cause for the convulsions was found and the patient came to the conclusion that she was a hopeless epileptic. In spite of the fact that she had been in the hands of many physicians, none of them had taken the trouble to explore her past life beyond a few perfunctory questions.

An analysis was undertaken. Space will not permit the reporting of the progress of the case in detail but it may be summed up by saying that she had had a frightfully unhappy childhood under the domination of an unusually cruel stepmother and that this had colored her whole subsequent emotional life. As a child the patient, Cinderella-like, had been made to slave in the interests of her younger step-sisters and had been taught to believe that she should always give way for someone else. Starved while her sisters were fed plentifully, the patient stole from the pantry night after night and then cried herself to sleep thinking that she was a wicked girl. At 21 she fell in love and the world looked brighter. Her mind pictured a happy, normal existence—a home, husband, children. But the object of her affection was engaged to another girl whom he did not love. He told the patient that he would break his engagement and marry her. But the second woman was a friend of the patient's and hadn't she been brought up always to sacrifice herself for others more worthy than she? And so, in the end, she gave up the man she loved and refused to marry him. She then determined to forget him and began training to become a trained nurse. She would thus be devoting herself to the service of others who were in need. Then the backaches began. Through the medium of dreams early forgotten memories were recalled. These memories were frequently of unjust and inhuman treatment at the hands of the stepmother. Among other episodes recalled was one in which the stepmother had kicked the patient in the small of the back after a severe scolding for something the patient had not done. The helpless little girl had felt that she would have killed her had she had the means—a wicked thought and one that had to be banished from the mind of a girl with strong religious principles. Another dream dealt with a time when she was stripped and beaten across the back with a whip in the presence of her older brother. Other dreams revealed the fact that the patient was still in love with the man she had refused and whom she thought she had forgotten. And here is another example of the work of an unconscious factor. When

denied normal wifehood and parenthood, the patient had tried to do something she really did not want to do. A neurosis developed which prevented the accomplishment of this substitute existence and a symptom appeared which symbolized the cruelty of the stepmother, the cause of all her trouble, and her hatred for her.

This is another case of hysteria and one which was much more serious in every way than case 1. Even after many conferences, during which a good rapport had been established, ordinary questioning failed to bring out the essential emotional conflict because the patient herself had repressed it. It was only by the use of dream analysis that this conflict was revealed. As the patient gradually recalled early forgotten memories and changed her point of view toward her stepmother and other things, her symptoms disappeared. She is leading a normal, active life today and has not had a convulsion or a pain in the back for over four years.

CASE III

A young married woman complained of general "nervousness" and "cystitis." She had all the symptoms of this latter condition in a mild form and had been cystoscoped many times by a very capable urologist, who told her that her bladder appeared normal in every way and that he could find no reason for the frequent return of her symptoms. But although he had seen her off and on for several years, he had never inquired into her sex life beyond a few brief questions such as "is everything all right between you and your husband?", to which she responded that it was. But, as a matter of fact, it was not. This patient wanted to live, like Peter Pan, in the Never-Never Land of childhood and insisted on continuing to live with her mother after she was married. She hated children and did not want any and she grew up with the belief that all sexuality was "bestial" and "nasty" and resented the fact that she had to have intercourse. Her husband was thoughtful of her feelings and made few demands upon her. And then she discovered that every time they had coitus she developed frequent and painful urination the following day. This necessitated expensive and disagreeable treatments. Wouldn't it be better not to have intercourse so frequently? And so, once more, we find an unconsciously produced symptom helping the patient fight against an undesired adult adjustment.

The treatment of this patient was very unsatisfactory as she refused to believe that her sexual maladjustment and childishness had anything to do with her bladder trouble or general nervousness. Sick and suffering as she was, it was easier for her to live thus than to make the adjustment to her husband and to life in general which her age demanded.

CASE IV

A young married woman complained of "heart trouble," which was characterized by fainting spells. These occurred whenever she was under any emotional pressure. She had been the oldest of 10 children and the only girl. Her father was a chronic drunkard and, from a very tender age, the patient had been accustomed to hearing her drunken father making sexual demands on her mother and had lain in bed shivering with fear and disgust as she heard her mother plead with him. She had seen the economic struggle to raise a large family on a small income and had early decided that she would never marry. Then, as time passed, she became conscious of the biological urge to marry and experienced a sexual thrill in company with men. It was at about this time that she began to have fainting spells and she then thought that

she wasn't strong enough to marry and have children, although she greatly desired them. She did marry but with the fixed idea that sexual relationship was only justified in the interest of having children. At the physical consummation of her marriage, she had hysterics and the whole "honeymoon" was a nightmare. For eight years the sexual relationship between her and her husband was entirely unnatural and she would almost always have hysterics—crying, scratching and biting her husband and often ending up with a fainting spell. It was necessary for her to change her attitude toward the whole matter, a painful process for her. But she went at it in good spirit and has not fainted but once in over two years. In addition to this, she also states that she never knew what happiness was before and all her "nervousness" has ceased.

It is certainly far from true to say that all cases of nervousness have a sexual basis but many of them undoubtedly have and it was the underlying factor in this case. From an early age the patient had looked forward to the sexual act with dread and loathing and her sexual life with her husband was most abnormal. Just why her difficulties in this field produced the particular symptoms that she showed would be hard to prove but they all disappeared when her sexual life became normal.

CASE V

The patient complained of general "nervousness" and painful menstruation. In giving her history she stated that she had always had some pains with her periods but that they had been particularly severe for the past six years. She had been married about a year before and had submitted to a suspension operation in an attempt to gain relief. This had done no good and the pains had been worse, if anything, since that time. She had also found that the sexual relationship was becoming very distasteful to her and she regretted this as her husband upbraided her for not loving him as she should. His own love for her was very evidently beginning to cool. Inquiry revealed that she had been greatly tempted sexually about six years before and had several times permitted certain friends to take liberties with her that her ethical ideals condemned. She had had a terribly guilty feeling even during the period when she was permitting these intimacies and had often thought of suicide. When she married she wanted to tell her husband of her "sins" but he would not let her and she felt that she was deceiving him as to her morality. The whole subject was frankly discussed but nothing was suggested as to the effect this clearing up of a sore spot might have on her dysmenorrhea. After her next period she said, "You know, it's a funny thing but I had scarcely any pain for the first time in years." Other periods have passed and she has been almost entirely free from the severe pains that crippled her. Not only this, but she has experienced a complete change in her enjoyment of the sexual act. Naturally enough her husband has again taken interest in her and has ceased to question her love for him. No suggestion was made as to the possible relationship between the guilt feelings of six years and her menstrual and marital difficulties but the confession of those feelings and a sympathetic discussion of them has apparently cured both the troubles of the mind and body whereas surgical interference accomplished neither.

This case is of particular interest because it shows that such a common complaint as dysmenorrhea may at times be due to an emotional conflict. These conflicts so frequently have to do with sexual matters that the physician is neglecting his duty if he fails to inquire into them. This patient, like so many others, had never been asked anything about her sex life beyond a few perfunctory questions. Physicians hesitate to ask ques-

tions dealing with the sex life of their women patients and yet most women will talk about this subject very freely if their confidence is won and if they understand that this subject may have a very important bearing on their complaint

CASE VI

A married white woman of 27 presented a picture of complete nervous collapse. For four years she had gradually been getting worse until, at the time she was first seen, she was hardly able to lift her head from the pillow or take food. She had lost many pounds in weight because of her severe indigestion, she had lost all interest in things and people, including her husband and son, and was intensely irritable and on the verge of tears. She had received no help from the many physicians to whom she had gone. Most of them had told her that she was "just nervous" but one of them had gone so far as to remove her appendix, which proved to be normal in every way. It was soon established that she and her husband had been practicing coitus interruptus for many years and that she was absolutely frigid while he was very passionate. And yet these matters had never been inquired into by any of the medical consultants and the patient and her husband had not liked to ask how to prevent conception in any other way. The patient was a very immature young woman emotionally who had always been spoiled by a doting mother. She had many peculiar and childish ways of looking at the world, from the difficulties of which she had always shrunk. She and her husband were polar opposites in psychological type and could not understand each other's way of doing things. One's way of doing and looking at things seemed unreasonable to the other. Thus, in spite of a very real affection between them, there were constant misunderstandings which caused friction and unhappiness. Both the patient and her husband felt that they were drifting toward a separation in a perfectly senseless way and yet they felt powerless to help themselves. A psychological reeducation of the patient was undertaken. Gradually a more normal sexual life was established, a more mature way of looking at the problems of her life was developed and the patient and her husband reached a better understanding of each other. With these changes came a return of strength and health, interest in life and love for her husband and child. The patient now has a second child and is leading an unusually active existence.

This patient presented a typical symptom-complex of neurasthenia. She was typical of that class of patients of whom Sir James Paget said, "The patient says she cannot. Her friends say she will not. The truth is, she cannot will." Weak and sick in body, she was spiritually unhappy and her marriage was drifting rapidly upon the rocks. In handling such cases, the physician must strive not only to bring back physical health but he must also teach his patient a new way of life.

SUMMARY

In treating functional nervous cases, the physician cannot neglect to study the mind as well as the body. If he does, his patient is apt to drift away into the hands of a quack, who uses strong suggestive therapy and thus cures him temporarily. Psychotherapy must be used as well as other kinds of therapeutics in order to attain that for which the ancients strove—*mens sana in corpore sano*. This is a necessary goal for the neurotic, for a sick mind is almost certain, sooner or later, to produce a sick body.

THE MEDICAL ASPECTS OF NATIONAL HEALTH INSURANCE¹

By GRANT FLEMING, M D, *Montreal, Canada*

NATIONAL Health Insurance is a very live topic today. What is more, it is a very serious thing for the medical profession at large, if not for the public. It is well that we should understand it properly, that we should have some conception of the forms it may take, and it is further important that we, as medical men, should be prepared to advise our governments and communities as to the manner in which it should be conducted—should it eventually come to pass as a government measure or as a service to the community.

It has often been said that medicine is a science and an art. Not often enough, however, has it been pointed out that medicine is a service. Osler has expressed it well. "Medicine," he said, "arose out of the primal sympathy of man with man, out of the desire to help those in sorrow, need and sickness."

Is it not reasonable then that service should be stressed as the outstanding feature of medical practice?

Medicine is not an isolated science, it is rather an assemblage from all the sciences which contribute to an understanding of health and disease in the human being. The application of medical science during recent years has been one of the worthwhile achievements in that it has minimized human suffering, increased the average span of healthy years, and thus added materially to the sum total of man's efficiency, effectiveness and happiness.

Medicine will always be conservative, this is to be expected for it is usually influenced, if not controlled, by those who have passed that period of life which welcomes change, the leaders are experienced and know the sobering effects of personal responsibility for human life.

Change is much more gradual than it appears to be in retrospect. Sydenham (1624-1689) is known as "The English Hippocrates." This one man marks for us the break from Galen's dogmatism, which had enslaved medicine for fifteen centuries, to a philosophical consideration of disease, and his era witnessed a return to the Hippocratic method, the study of the individual patient. Sydenham marks the change, but Sydenham was, after all, only the product of his time, not the instigator of the movement. As you will recall, Boerhaave (1668-1738), at the same period, played a similar role in Holland.

¹ Delivered before the American College of Physicians, Chicago, Ill., April 18, 1934

On this continent, the practice of medicine, while perhaps apparently unchanged, has nevertheless undergone a very marked alteration in its method. Today, organized medical services, of one kind or another, have become established on a very extensive scale so much so, indeed, that much discussion has evolved as to whether or not, in the near future, the new world will emulate those older countries abroad which are now providing, under one name or another, organized medical services.

Sickness is not a personal matter in the sense that its effects are limited to the patient. A communicable disease is spread from the sick to the well. Sickness means loss of income to the patient and decreased production to the community. The vicious circle of disease, poverty and dependence is only too familiar. Obviously, sickness is a national social problem, the cost of which we pay, either directly or indirectly, in every instance.

Glance, if you will, at the vital statistics of this or any other community, and you will find that a large percentage of the deaths which occur may be classified as preventable, and why? This condition of affairs exists because of a universal failure to bring together medical knowledge and medical practice. The most urgent problem in medicine today is not the accumulation of further knowledge, desirable as that undoubtedly is, but to bridge the gap which now exists between knowledge and practice.

This gap is not a new chasm caused by the upheavals of an economic depression. It existed even in our years of prosperity, and it has merely been widened by the depression.

Today, more than ever before, we are concerned with medicine as a service, as one of the social resources of mankind to be used for the benefit of all the human family. In other words, conditions must be so changed as to make the full benefits of curative and preventive medicine available to each and every individual. How is this to be achieved? What are we going to do about it?

A number of explanations may be offered to account for the present undesirable arrangements whereby so many are left without the medical care they need. I believe that the real explanation is to be found in the fact that there is no effort made, under our present system, to overcome the economic barrier which now keeps patient and doctor apart.

The problems arising out of the costs of medical care are usually presented from the point of view of the public, as consumers. We are told that, because sickness is not evenly distributed over the population, in consequence, the costs of sickness are not evenly distributed. We are reminded that, as sickness is unpredictable as to its time of occurrence, severity and cost, it cannot be budgeted for. Furthermore, it is pointed out that wage-earners, who make up the bulk of the population, have, as a rule, no financial resources beyond their weekly earnings. The situation, too, is further complicated by the fact that sickness is most prevalent in the lower income groups. All told, this creates an impossible situation, with the heaviest burden resting on those who are least able to bear it.

There is, of course, a practitioners' point of view to this question of costs of sickness. If the public are unable to pay, the doctor cannot collect the fees he has earned. The sliding scale of fees is used to adjust the fee, according to the medical attendant's judgment, to the ability of the individual or family to pay. Why should a medical practitioner, on this basis, charge his full fee to a thrifty family who, because of their thrift, are able to pay, and reduce his fee to a careless family who, because they are spend-thrifts, are unable to pay? This rather obviously gives an unfair advantage to the prodigal and penalizes the thrifty.

If the sliding scale is to be effective, the physician must be capable of assessing ability to pay. It is also presumed that each medical practitioner will have an equal share of practice among all economic groups in order to even out his fees. Unfortunately, the larger the practice among the poor, the less time or opportunity is there to build up a clientele of well-to-do patients. In any case, it is an unsound economic system to overcharge one individual to compensate for the loss incurred through others, who pay less than the cost of service.

The situation from the point of view of the medical profession is made difficult too because our present system fails in not making adequate use of the recently-qualified medical practitioner. The result is that the whole of the individual doctor's life earnings must be made in a comparatively few years.

Nor is this all, for it has come to be expected that the medical profession will assume the obligation of the State in providing indigents with one of the necessities of life, medical care. Surely it is unsound and unfair that one group, the medical profession, should be made to assume a burden which should be borne by the whole community.

The medical profession are proud of their record of gratuitous service to those who are in need. The members of the profession, in general, are always willing to give a certain amount of free service. Such free service, however, should be entirely voluntary, as is given whenever a doctor provides care beyond that for which the patient can pay.

The problem which faces the public and the medical profession may be briefly stated to be the provision of adequate medical care for all, with reasonable remuneration for those providing the medical care, by making it possible for all to contribute their share of the cost.

National Health Insurance is suggested as one means whereby this problem may be solved. The principle of health insurance is, in a word, to shift the economic burden from the individual to the group. The insured pay a premium to a fund out of which the costs of medical care are met.

I should like to deal with two special features, because a lack of understanding of these distorts the whole consideration of national health insurance.

First and foremost is the fact that the public desire a high standard of

medical services and, at the same time, approve of a reasonable remuneration to the doctor for that service. The public realize, too, that it is they who would suffer most from any lowering of standards. The medical profession, on their part, are anxious to provide medical service of a high standard, and, in return, are entitled to expect a reasonable remuneration.

Secondly, the public evince no desire to interfere with the professional side of medical practice, they are willing to meet the desire of the profession to retain full control in this matter.

There is no public dissatisfaction with the medical profession, indeed, we find the very reverse. The public show an appreciation of medicine and a desire to profit more fully of what medicine has to offer. Public dissatisfaction is concerned with the system of medical practice whereby the benefits of medicine are not available to all.

If we start with an appreciation of these truths, we can then view the medical aspects of national health insurance without the bitterness and lack of understanding which arise if it is presumed that the public and the medical profession are at loggerheads over such basic principles of any system of organized medical services.

The medical aspects of national health insurance cannot be entirely divorced from other matters, such, for example, as organization, because of the relationship between organization, costs, et cetera, and the medical services that are to be provided.

The members of the medical profession unfortunately are apt to be extremely individualistic in outlook. The individual practitioner frequently builds up a rather quaint conceit, based upon the adulation of his patients, displaying a complacency that is amusing but revealing, and, above all, an irritation that anyone who has not successfully passed through the fires of medical training should dare to voice an opinion on the subject of medical care.

The medical profession, after all, hold a strategic position in national health insurance because they have a monopoly of the knowledge concerning the main field of service which it is the aim of health insurance to provide. But just as physicians in public health have learned that their group is but one of several contributing to public health services, so must the practitioner of curative medicine come to realize that medical practitioners form but one of several groups taking care of the sick.

If it is desirable, and I believe that it is, that the organized medical profession control the professional side of the medical services in national health insurance, it is just as logical that, in matters of business arrangements for national health insurance, the lay power be supreme.

The relationship is comparable to that which exists in our hospitals between the Board of Governors, a lay body, and the Medical Board, a professional body. This relationship, despite certain difficulties, works very well, and there is no better system to suggest unless a dictatorship is preferable.

While I hold no special brief for national health insurance, yet, up to the present time, it would seem to be the one method of spreading the costs of medical care which has already been used extensively on a national basis. A number of countries have tried health insurance, and while they make many criticisms of it, not one has given it up, and most have extended its scope. A fair conclusion is that they have, at all events, found health insurance to be preferable to the conditions which existed previously.

The organized medical profession have the right to expect that they will be consulted by any government considering health insurance or other legislation affecting the provision of medical care.

Obviously, there is nothing to be gained by a government's consulting a medical profession whose members have no suggestion to make and no opinion to offer beyond the expression of a pious hope that all will be well if things are left to take care of themselves.

Medical practitioners are given few opportunities to use their skill in keeping people well. It seems unlikely that any large percentage of the population will, as individuals, pay fees for health supervision. The payment of medical fees will always be more or less irritating, because we prefer to use our money to buy something we really want.

There has been a considerable amount of annoyance shown by the medical profession over the invasion, by public health services, of what the profession have considered to be the field of private practice. It is only fair to note, however, that the encroachments which have been resented have usually been into fields left unoccupied until the way was opened by the public health services.

A fair criticism of national health insurance is that it has not been preventive either in outlook or in practice. Health supervision on an individual basis is certainly more desirable and should be more effective than a health clinic service.

National health insurance should signify more than lip service to the desirability of prevention, it should mean the systematic practice of preventive medicine by the medical profession. The health insurance practitioner would be paid for his preventive work, and the economic barrier raised by direct fees would be removed from the path of the patient who wishes health supervision in his doctor's office.

It is impossible to provide an adequate medical service without a properly organized health department. It would be possible, with national health insurance, to define the two fields of public health and private practice. No gaps between them need exist. There need be no duplication, and most of the sources of irritation as between the public health services and the practitioners of medicine would be removed. The allotment of health supervision and active immunization to the general practitioner is both desirable and practical, provided the service is paid for.

There are some disease problems which may best be dealt with through clinics of the public health services. Tuberculosis, venereal disease and

mental hygiene require the active participation of the public health nurse, working in and from the clinic, to interpret environmental conditions to the physician and to see that his instructions are carried out in the home. Clinics in these fields are rightly regarded as being essential in the programme for prevention and control.

Mass methods are not applicable to medical care. Neither patient, nor disease, nor treatment can be standardized. Medical care, to be effective, must be rendered on an individual basis.

Experience shows that the best type of medical care is built around the general practitioner. The first objective of national health insurance should be to make available, to all, the services of a general practitioner.

A good deal of sentiment surrounds the title, "family doctor." The centralization which has resulted from modern transportation, along with other forces, has brought to an end the social organization into which the family doctor fitted. The old-time family doctor passed when medicine advanced beyond the acquirement of personal skills.

The general practitioner of today is quite capable of dealing with over 80 per cent of illness. The present tendency of supplanting the general practitioner by a group of specialists, called by the family according to the age of the patient or the part which appears to be diseased, is unsound.

It is the general practitioner who deals best with the individual patient, whether it be as health adviser or to prescribe treatment, because his is the all-round approach that is based upon a general knowledge of his patient's physical, mental and social condition. It is this more intimate general knowledge of his patient which allows the general practitioner to be effective in the psycho-therapy which so many patients require.

Specialism has modified medical practice. Partially or wholly, temporarily or permanently, some branch of modern medicine is restricted to the specialist by reason of his more complete knowledge and skill in a limited field.

Unfortunately the public go to specialists direct because they find more and more medical practitioners refusing to do general practice, with the result that the public have come to regard the general practitioner as being of inferior quality. The public have also observed that hospital staffs are largely made up of specialists, and the public have found the specialist not unwilling to receive patients without any reference from a general practitioner.

To emphasize the rightful place of the general practitioner is not to minimize the need for the medical specialist and consultant. It seems reasonable that a general examination should precede special examinations, and that a correlation of the findings of special examinations should be made from a general rather than from a special point of view.

National health insurance should require that specialists be designated and that they receive their cases through the general practitioner who seeks their assistance in problems of diagnosis or treatment, and, in certain cases,

to provide the therapy indicated. The general practitioner, under such circumstances, takes on many of the functions of the old family doctor, including that of advising his patient as to where competent specialist service, of the kind required, can best be secured.

Much sentimental nonsense has been expressed about freedom of choice of physician. Freedom of choice is desirable because it means the confidence of the patient in the doctor of his choice which is such a valuable element in medical treatment. Free choice means competitive practice which, since it tends to maintain standards of service, is, within limitations, most desirable.

Real freedom of choice of medical attendant is exercised today only by that minority of the population who can have what they want because they have the money to pay for it. Geographic location and economic status limit freedom of choice in a fairly drastic manner for the majority of people. The only freedom of choice, alas, which most of the people now exercise is to decide when they are "sick enough to have a doctor."

National health insurance would make freedom of choice of physician much more of a reality, because every qualified medical practitioner should be eligible to practice, and the economic barrier would be removed. I believe that if the individual relationship between doctor and patient is to be preserved under our social organization, the only way open is to remove the economic barrier of medical fees which now keeps patient and doctor apart.

The need for health insurance grows out of the inability of the individual or family to make economic provision for medical care. The insured group should be limited to those with an income below a figure which makes it unlikely that they can, individually, make provision for illness. It is difficult to set an arbitrary amount, but an income of twenty-five hundred dollars for those with dependants, and twelve hundred dollars for those without dependants, might be considered.

Under our present social organization, there is no reason why the medical profession should be treated differently from the other professions when it is a question of dealing with the well-to-do. For that group, the question of fees should be a matter of personal arrangement between the patient and his medical attendant.

However, there is no reason why those of the well-to-do group should not, if they so desire, insure themselves against hospital costs, which are a major factor in the economic problem of medical care for those above the health insurance income level.

Sickness insurance was originally intended to provide a cash benefit in lieu of wages lost on account of illness. Later, medical care was provided, and now we have arrived at the time when it is advocated that the only benefit which health insurance should provide is adequate medical care for the insured. Adequate medical care means a complete service, at home and in hospital, by doctors, dentists, nurses and auxiliary services.

It is unfortunate that illness of the breadwinner usually means a loss of

income at the very time expenses are increased as a result of the illness. Nevertheless, it is believed that whatever cash allowance is to be provided, to compensate for lost wages, should be paid out of unemployment insurance and not out of health insurance.

The cash benefit has been the cause of most of the difficulties associated with health insurance. It brings in the question of certification, it drains the health insurance fund financially, and, all told, makes administration and finance unduly difficult.

The medical profession are desirous of divorcing health insurance from all benefits other than that of medical care. To do so makes the service clear-cut in its purpose. The medical profession are not particularly concerned as to the "insurance carrier" except in that they would be unalterably opposed to allowing any insurance carrier to come between the doctor and his patient as regards the professional side of the doctor's services.

Public and profession would unite in demanding that national health insurance should place in the hands of the organized medical profession responsibility for the control of the professional side of the medical benefit. In no other way can the public be assured of a high standard of medical care, available as required, leaving the medical profession free to maintain such a service and, at the same time, to discipline its own members. The best results are obtained by giving responsibility to those who provide the service. Individualism can be carried to impractical extremes, and in any organized service, there must be some control and provision to take care of the few recalcitrants found in every group. Beyond that, there would be no change from the present mode of practice. The medical practitioner would have his private patients and would care for his insured clientele as private patients, except that, for their care, he would be paid out of the insurance fund.

The medical care of the indigents is a responsibility of the State. All the arguments advanced in favor of freedom of choice of physician, et cetera, as being essential to the provision of adequate medical care, are equally valid as regards the medical care of the indigent.

Obviously, it would be undesirable to build up two systems of organized medical services, the one for the insured, the other for the indigent. A satisfactory way would be for the State to pay the insurance premiums of the indigent, and thus discharge an obligation, long overdue, to provide the indigent with medical care at the expense of the public as a whole, and to remunerate those who provide the care.

The general principle of payment on the basis of service rendered receives universal support. There does not appear to be any reason for a hard and fast rule as to how health insurance practitioners are to be paid. A certain sum of money will be available for the payment of the practitioners, and there is no good reason why the doctors of each area should not, themselves, decide as to which method they desire to use.

In those areas where there is not a sufficient population to support even

one general practitioner, it appears that some definite salary must be paid to the doctor so as to assure the area of a medical service and the practitioner of a certain income

In England, the medical profession have selected payment on a capitation basis, which is the payment of a *per caput* allowance for each insured person

In some countries, small fees are charged for a permit to secure medical care when illness occurs, or part of the cost of medicines is paid for, direct, by the patient. The purpose of all such fees is to discourage abuse of the service. It is, however, a serious matter to impose any fee, no matter how small, because the object is to remove the barrier of fees and not to discourage the insured from consulting his doctor. Better some abuse than the loss to anyone of the benefit of early diagnosis and treatment

In conclusion, let it not be forgotten that it is the public—the great consumers—who, ultimately, are going to decide what they are prepared to pay for. This is not the responsibility of the medical profession, they cannot attempt to force upon the public a service for which the public are unable to pay

Still more important, perhaps, is it to emphasize the fact that it is not the responsibility of the medical profession to furnish a service for which the public are able but unwilling to pay. On the other hand, the medical profession should not deprive the public of medical care for which the public are able and willing to pay through National Health Insurance

EDITORIAL

UNIVERSITIES AND MEDICAL PATENTS

At the recent meeting of the American Medical Association at Cleveland, Dr George Blumer introduced a motion, which was passed by the House of Delegates, requesting that a committee be appointed by the Board of Trustees to make a comprehensive study of the situation as to the control of patents covering products and devices used in the practice of medicine.

One of the finer traditions of the medical profession prescribes that the physician shall make freely available to his colleagues and to the public any new medical knowledge which he may have gained, and shall not attempt to restrict the use of this knowledge for purposes of personal advantage.

However, in the last decennium, there has developed on this continent a practice by which the physician patents a medical product or device and then assigns the patent to the university in which he is working, or to some incorporated body allied to the university and created for the purpose of controlling such patents. The university or the allied incorporated body may then market the patent by licensing one or more firms to manufacture and sell the product. Royalties may be paid to the university by such licensees. These royalties may be used to conduct a laboratory in the university to check the character of the product produced by the licensees, they may also be devoted to further research on the product, they may be allotted to general research purposes, and they may be in part expended in payments made to the discoverer or inventor.

This practice is, of course, not confined to the schools of medicine, indeed it is more common in other research departments, as for example in colleges of engineering. The medical patents, however, constitute a special instance since the patenting of medicinal products by medical men appears to violate the traditions of the medical profession. It is no doubt in part for this reason that the American Medical Association is being requested to study the situation. It is also, however, because there are grave doubts in many minds as to whether the very nature of university research will not be altered if financial advantage is to be sought from the outcome of that research.

The purposes for which universities or allied corporations may take out patents are very varied. They may be roughly classed as follows:

- (a) Patenting to ensure financial profit to the discoverer or inventor
- (b) Patenting to ensure an income to the university in which the discovery or invention was made
- (c) Patenting to protect the public against inferior products
- (d) Patenting to prevent, by dedication of the patent to the public, any monopoly being established by a commercial agency

A study of the statements made by universities shows that one or more

of the above purposes are advocated by those whose policy includes the patenting of medical inventions

Patenting to Ensure Financial Profit to the Discoverer or Inventor It does not appear that any university has set up machinery for the administration of patents for the sole purpose of procuring financial profit for the discoverer of the method, substance or device which has been patented. However, in several universities or their allied corporations, the policy has been adopted of allotting some share of the profits to the inventor and in some instances no distinction is made in this respect between medical and non-medical inventions. It may be fairly said then that such institutions have adopted a policy which contravenes an old medical tradition.

This tradition that personal profit must not be derived from a medical discovery is adhered to, it must be remembered, not only by the faculties of medical schools but by the far larger number of physicians who are in the practice of medicine outside of these schools. This tradition and that of free service to the poor are potent factors in attracting into the profession men who view their life work as of a higher order than a trade. It would be a sad loss to the world if such men were to be replaced by a type that felt that money was a sufficient recompense, and that for money alone without the ennobling idealism of the finer traditions of the profession, they would be willing to perform the menial and often repugnant personal services that are a part of the physician's task. The men who bear the brunt of these daily demands are those who are also called on to devote much of their time to free work. In a few instances their income is large, on the average it is little more than the salaries of medical research men. This great rank and file of the profession who have lived up to their part of the medical tradition, that of free service, have felt pride in their colleagues in the laboratory who have refused to profit personally by their discoveries. A tendency on the part of these latter to shatter this fine tradition will be a deep hurt to every true physician, a loss of something spiritual that helped him over the sordid parts of his work.

Patenting to Ensure an Income to the University in Which the Discovery or Invention Was Made The governing bodies of a number of universities have stood by the medical tradition for individuals and have refused to permit their institution to profit from the sale of medical inventions or discoveries. Others apparently feel that such funds are acceptable provided that they be devoted to scientific research.

It is perhaps best not to discuss the ethical questions raised by an institution of learning financing itself by adding to the cost to the public of medical remedies, or to do more than allude to the possible loss of dignity involved when such an institution, which is tax free because it does not operate for profit, manages to secure itself profits from its laboratories by the device of an allied corporation that manages its patent business.

Attention may be drawn, however, to the inequitable distribution of financial rewards that seems certain to occur under any régime of university patents.

It would for example be manifestly unfair if one university were to derive financial profit from work carried on in another institution, and yet just this situation is bound to arise if one institution, which does not patent, publishes its results freely thus enabling another institution, by adding some minor practical adaptation to this work, to take out a patent upon it. It may be predicted that such injustices between institutions will occur until all have adopted the policy of taking out patents or all have forsworn the practice.

Even if, however, all medical schools and institutions were agreed upon a policy of obtaining patent rights upon products discovered or invented in their laboratories it is highly questionable whether in the case of patents on the biologic products the purposes of true equity of return as between various individuals and various schools would be attained under the provisions of the present patent laws. Patents are granted not for the discovery of general laws but for the invention of a device, a method, or a product whereby the principle may be applied. The devising of such a means of application is often of very minor scientific merit as compared with the discovery and proof of the general principle. Yet, were one school to devote its resources in men and material to research on the principle, which is not patentable, the total financial reward might yet go to another institution which made a hasty application of this newly discovered principle, and obtained a patent covering such application.

Our patent laws moreover allow of basic patents which cover not only what is the known method of applying the device or product but all future discoveries in which the basic principle employed is similar. The possible injustices inherent in such basic patents are well illustrated in the instance of the Steenbock patent cited by the British Medical Research Council. This patent, which is owned by the Wisconsin Alumni Research Foundation, covers the process of producing vitamin D in natural substances by irradiation with ultra-violet light. The process was originally applied by Dr Steenbock to the irradiation of foodstuffs. Later, according to the Medical Research Council, it was discovered in England that the provitamin in these natural substances was ergosterol and that the irradiation of pure ergosterol resulted in a product many thousand times more potent in vitamin D than any previously known. English manufacturers found, however, that the Steenbock patent covered the irradiation of any substance and accordingly to take advantage of an English discovery the English must pay tribute to a corporation allied to the University of Wisconsin.

Those who defend this money making function of universities apparently assume that it will have no deleterious effect upon the character of the scientific work in the universities or upon the prestige of the university in the community. One may be permitted to express grave doubts of the validity of these assumptions.

A scientist who has no plans to earn money for himself or his school by his work usually enjoys discussing his results freely with others. Who doubts but that from such free intercourse valuable new ideas are developed?

How ready will the same man be to suggest to another an idea that has a patentable value which he himself might profit by?

No one doubts but what the prime function of the research departments of a university is to develop science, and not the practical applications of science. There are great laboratories and highly trained men at the command of industry to devote themselves more exclusively to the latter objective. It is apparently assumed, however, that since in the university laboratories the practical applications of science are inevitably studied as a part of more general investigations, the university may profit from these practical results of the work, without affecting the interest of the scientist in the broader aspects of his problems. But one wonders whether the measure of a man's university standing will not be insidiously influenced by considerations of the monetary value of his work. Will it be possible not to recognize his contribution to the university funds by according him more weight in council, a more definite right to advancement, perhaps a larger salary? Will there not be envy and bitterness between departments which have profited through patents by increased facilities, a larger staff, more secretarial help, etc., and those whose subject matter contains nothing patentable? Will not the general direction of research in universities be deflected from the goal of all of the truth for its own sake, to that of the part of the truth that has a possible cash value?

It may prove unwise also to assume that the public esteem of the work of scientists will remain as high when it is known that the scientist or his institution has a financial interest which would be affected by the outcome of his researches. There are no doubt individual scientists whose personal prestige is too great to be influenced even by such circumstances. The majority, however, would find that their statements had been trusted not because it was felt that they more than other men were above personal bias, but only because it had been considered that their university position removed them from any temptation.

It seems very doubtful whether the application of additional income from patents to research possesses advantages to counterbalance the restriction of scientific discussion, the inevitable instances of unjust awards, the increase in the lure of applied science, and the loss of confidence on the part of the public which may be reasonably expected if the policy of procuring funds by patenting medical products is widely adopted by our universities.

Patenting to Protect the Public Against Inferior Products It is often stated that one of the valuable ends served by university patents on medical products is the protection of the public against the premature general distribution of dangerously potent remedies, and against inferior products. It is admittedly to the advantage of the public that certain drugs and biologic substances should receive extensive clinical trial under adequate control in some of the large university hospitals so that their value and dangers may be learned before they are placed on general sale. To obtain the material for such trials it is necessary that large scale production methods be em-

ployed and the cooperation of manufacturing firms may be essential. These in return may rightfully expect an advantage in the way of an exclusive license for a time to market the product. A patent may, therefore, be necessary to make it possible adequately to test a dangerous remedy. There may at times also be an advantage to the public if the manufacture of an unusually complex drug or remedy is restricted by the license method to those firms which agree to submit their products to the check of an assay in the university laboratories. Such measures may occasionally be necessary but they certainly should be looked upon as of a temporary and emergency nature and not as a proper function of the universities. If there is to be systematic testing of the therapeutic and the toxic properties of drugs and other medicinal agents on the market it should certainly be carried out on all important products by some governmental agency with power to forbid the sale of substandard goods. At least, however, where a university administers a patent in order that adequate testing of the product be made possible, and receives in return only the extra funds it has disbursed, its motives are plainly above criticism.

At present, it may be remarked, certain drug firms are extremely anxious to be licensed to market any drug or foodstuff the patent of which is owned by a university, and they are especially aware of the advantage of being able to state that each lot is assayed in the laboratory of the university. To obtain the advantages of these good advertising points they are quite willing to furnish in royalties the necessary funds for establishing the laboratory in the university and for subsidizing further research which, they must naturally hope, will still further prove the value of the product in question.

There seems to be ground for criticism in this latter feature—the acceptance of royalties to carry on research on a product already on the market. Ordinary men, even scientifically trained, should not be appointed to work on a problem when the publication of unfavorable results might cut short the source of their own salaries, and when they must constantly feel impelled to hang over the laboratory door the old motto "*Hôm soit qui mal y pense*."

Patenting and Dedicating the Patent to the Public. The criticism is frequently offered that if the medical research worker does not patent his invention it will be patented by some one else who may then establish a monopoly and thus make the public pay far more than they would have had to if the patent had been assigned to a university. If a patentable process or method has been published by one man it can only be patented by another if he modifies it fundamentally. However, since this may occur, a number of scientific men in the past have taken the step of securing patents as a matter of record and then throwing them open gratis to public use. This has not always accomplished all that was hoped for since manufacturing firms have been chary of investing the necessary funds for machinery and for advertising when they had no protection against competition. It is questionable, however, whether any really important medical discovery if patented in this way would be allowed to go undeveloped. Drugs and other

medicinal products possessing important new properties rapidly become self advertising and the demand for them is natural and continuous and does not depend on artificial stimulation. In the case then of important medical discoveries it would seem that the university might well encourage the inventor to patent and dedicate his patent to the public. Since the average medical research worker possesses neither the knowledge, the time, nor the means to obtain a patent, a group of alumni might be formed who would undertake this part of the task, feeling that thereby they were not only gaining friends and acclaim for their medical school but also helping to preserve a cherished medical tradition.

We wish well to the Committee of the American Medical Association. There is a difficult and an important task. The medical schools of the country are sharply divided on the point at issue. It is vital in the interests of equity as well as of good feeling that all should be united again. This can be accomplished, we feel, only by the abandonment of the policy of patenting medical inventions for profit.

The right to patent an invention is not a natural right but a privilege granted by the state to reward inventors. The medical profession as a whole have lived by the rule of relinquishing this reward in favor of the public. It would probably meet with the approval of the medical profession if, following the lead of certain other countries, the United States as a measure of public policy removed from the category of patentable articles all products and devices which are to be used by the medical profession with the purpose of curing or preventing disease.

REVIEWS

Recent Advances in Sex and Reproductive Physiology By J M ROBSON, M B B Sc (Leeds), F R S E, Beit Memorial Research Fellow, Institute of Animal Genetics University of Edinburgh With introduction by Prof F A E Crew, M D, D Sc, F R S E xv + 249 pages, 14 × 21 cm P Blakiston's Son and Co, Inc, Philadelphia 1934 Price, \$4 00

At the very outset it may be said that the present work is a thoroughly sound and acceptable one in every way, and that it may be unreservedly recommended not only to the laboratory investigator, but also to the increasing number of clinicians who are becoming interested in endocrinological problems. The text is introduced by a foreword from Professor F A E Crew, director of the Institute of Animal Genetics at Edinburgh, whose laboratory has been so productive in the field of reproductive physiology.

The author has arranged his subject matter very logically, and it is surprising how thoroughly he has condensed most of the available worthwhile information into such a comparatively small compass. The secret is obviously in the discriminating omission of discussions dealing with relatively unimportant aspects of the general problem. References to the literature are frequent enough but they are not allowed to mar the readability of the work, as is so often the case. The discussion of the rôles played by the ovarian and pituitary hormones in the cycle, in pregnancy and parturition, and in lactation, as well as the description of the associated cyclical histologic changes, is an excellent epitome of present-day viewpoints. It is perhaps natural that the subject of hormonal control of uterine motility and reactivity, to which the author has made valuable original contributions, has received rather fuller discussion than one might otherwise expect in a work of this size.

There is a short but probably adequate final chapter on Clinical Applications, including a description of the various pregnancy tests. On the whole, however, the chief appeal will probably be to the laboratory investigator wishing to familiarize himself with the present status of research in the field of reproductive physiology, and to the intelligent clinician, particularly the gynecologist and obstetrician, who has the same desire, because of the more intelligent approach to clinical problems which such knowledge makes possible.

Allergy in General Practice By SAMUEL M FEINBERG, M D, F A C P xv + 339 pages, 16 × 24 cm Lea and Febiger, Philadelphia 1934 Price, \$4 50

After reading this book one feels that the author has failed in his avowed purpose of enabling "the average physician to attain a simple direct approach to the handling of this group of ailments," and of showing him "how to care for the allergic patient," not because of any inherent faults in the volume itself but because his purpose is practically impossible of attainment. No branch of medicine is subject to so many variables as is allergy. Basically, one is dealing with a myriad of possible etiological agents, specific in nature, and the clinical effect of exposure to these is again subject to many influences as location, concentration, portal of entry, general health of the patient and many other subsidiary factors. As a result, successful study of these cases presents a problem, except in the simplest instances, that demands the guiding hand of broad experience in finding the significant factors among the multitude of confusing possibilities present in almost every case. No moderate sized book, no matter how well written, can ever hope to do more than present clearly the underlying factors involved in allergy, and this the author has undoubtedly achieved in the present volume.

The material in the book is well organized and is clearly presented. The plan of presentation adheres rather closely to the conventional, beginning with a brief but good historical chapter. There then follows a chapter upon anaphylaxis and allergy which rather satisfactorily explains the relationship between the two. One paragraph in this chapter, in which the author states that all manifestations of allergy are to be considered as being essentially the same, with the same causes, the same method of reaching a specific diagnosis and the same specific treatment, is worthy of emphasis.

His discussion of the importance of asthma in chapter three, in which he mentions the economic loss from asthma itself and calls attention to the disability resulting from its complications, is valuable in view of the laissez-faire attitude of some members of the profession toward this condition. The further consideration of the symptomatology, diagnosis and treatment of asthma follows the usual lines and is well presented.

The section on hay fever is well done and the discussion of hay fever pollens by Durham is especially fine.

The last chapter of the book, devoted to "other allergic disorders," is sound but too brief to be of much practical value in handling these cases.

The case reports are very good and should be most helpful to men just beginning this work.

In conclusion, one might say that, whereas the main purpose of the book is only doubtfully achieved, it can be recommended as giving an excellent brief presentation of the subject.

H M B

That Heart of Yours By S. CALVIN SMITH, M.D., Cardiologist. 212 pages. J. B. Lippincott and Co., Philadelphia. 1934. Price \$2.00.

Dr. Smith has written a number of books on the heart, and in this book he has discussed the heart for the laity. In 10 chapters he describes the normal heart and its troubles. He states "Although the conquest of heart trouble has been made by Modern Medicine, the conquest of troubled hearts rests largely with the individual."

He emphasizes the importance of the mind in considering heart trouble, and in his first chapter he points out the fact that many heart conditions that give the patient apprehension are primarily emotional. "It cannot be stated too emphatically at the outset of this book that heart protests are not heart disease. Better heart health is attained by easing its load, by lightening its burdens, by the proper interweaving of rest and exercise and by correct daily living."

In his next two chapters he discusses the hazards that the heart usually meets in childhood and adolescence and he emphasizes the fact that "the heart is subjected to unusual demands by the changing physiology of a growing body," and emphasizes the place that diseased tonsils play in heart infection.

In his next chapter he stresses the need for heart hygiene in middle life, and in the next two chapters he discusses "signs that may indicate beginning heart trouble and the use and abuse of heart rest," and concludes "When the heart is acutely ill, rest is paramount. As the heart recovers, exercise must be gradually introduced and increased as convalescence advances, if that heart is ever again to become strong and efficient."

In the next two chapters he discusses general suggestions for heart care and in special heart conditions emphasizes the need for temperance in everything, and states "Act your age."

Throughout this book the author has maintained a very sane position and says nothing that would create fear in the mind of the patient.

In his last chapter on "The Psychology of Reconstruction," he wisely states "Stop feeling sorry for yourself."

The physician could well add this book to his library to be used as psychotherapy in those all too common cases that continually come to his attention

J L McC

Modern Drug Encyclopedia and Therapeutic Guide By JACOB GUFMAN, M D, Phar D, F A C P, Consulting Physician, Manhattan General Hospital, New York, formerly Professor of Materia Medica, College of Dentistry, University of the State of New Jersey vi + 1393 pages, 17 X 24 cm Paul B Hoeber, Inc, New York City 1934 Price \$7 50

This encyclopedic compilation of information on drugs is designed to meet the demand of the physician for information concerning the most recent therapeutic agents placed at his command by the laboratories of medical and pharmaceutical research. The volume contains 8,160 modern, non-pharmacopoeial medicinal preparations, comprising 1,878 drugs and chemicals, 535 biologicals, 860 endocrines, 1,563 ampule medicaments, 209 medical foods, 129 mineral waters, 2,344 individual and group allergens and 642 miscellaneous products.

The arrangement of the individual drugs under the various subdivisions of the book is alphabetical. A monograph very similar to that used by the United States Pharmacopoeia or New and Nonofficial Remedies has been employed. Information regarding the physical and chemical properties and therapeutic merit is included. Dosage and method of administration form a special feature of each monograph. Besides the name and location of the manufacturer, information is given regarding the sizes in which the product is marketed.

In addition to the pharmaceutical arrangement and descriptive monographs mentioned in the foregoing paragraph, the book contains a therapeutic guide. In this, the drugs and preparations are arranged under headings which indicate their use in general therapeutics.

Many of the substances which have been the subject of research investigation or controversial medical opinion and discussion in medical literature have appended to them an adequate bibliography.

For convenience and rapidity in finding articles a commercial index has been included. In this, manufacturers are listed and under each heading a list of their specialties and products has been compiled.

In the opinion of the reviewer the volume shows evidence of thoroughness and extensive work on the part of the author. In this day of the passing of the nationally known dispensaries and with the prodigious list of new drugs placed on the market each year by enterprising manufacturers, there is definite need for a volume of this kind.

J C K, Jr

A Text Book of Pharmacology and Therapeutics By ARTHUR R CUSHNY, M D, LL D, F R S, 10th Edition Revised by C W EDMUNDS, A B, M D, and J A GUNN, M A, M D, D Sc 786 pages, 16 X 24 cm Lea and Febiger, Philadelphia 1934 Price, \$6 50

This tenth edition of Cushny's classical textbook appears both substantial in physical make-up, and enlarged in the quantity of subject matter. In the present edition changes have been made to conform with the British Pharmacopoeia of 1932. The authors point out also the inclusion of the newer knowledge on liver and stomach preparations in the treatment of primary anemia, the vitamins, iron medication, bismuth in the treatment of syphilis, new hypnotic agents and the recent advances in

the chemistry of digitalis. In this edition the section on the therapeutic uses of the individually considered drugs immediately follows the discussion of their pharmacological action. Another innovation is the inclusion of a short biographical note of the author in place of the usual preface to the first edition, to point out to the future generations that the "Man was greater than the Book."

The authors retain the general method of presentation, i.e. (1) drugs that are not absorbed, (2) drugs that act after absorption. In the opinion of the reviewer, the book might more effectively accomplish its purpose if the drugs were discussed under the heading of the physiological systems upon which they act. It is stimulating to see the newer theories of the action of drugs on cells mentioned in the text. Perhaps the widespread recognition of these theories will tend to bring about a more quantitative concept of drug action. The manner in which the section on narcosis has been brought abreast of the times is worthy of special mention. It is noted that the theory of Bancroft on narcotic action was not included.

Among some of the newer drugs that have been omitted from the text are dinitrophenol, divinyl oxide, trichlorethylene and tribromethanol. In the discussion of insulin it is observed that the work of Biasotti and Houssay on hypophysectomized-depancreatized animals is not included. It is to be regretted that in many instances the chemical formulae included show evidence of lack of careful revision.

In general it may be predicted that the text will continue to occupy the same important place in pharmacology and therapeutics that it has held for the past 35 years.

J. C. K., Jr.

External Diseases of the Eye. By DONALD T. ATKINSON. 704 pages, 479 illustrations. Lea and Febiger, Philadelphia. 1934. Price, \$7.50.

This book of 15 chapters is a welcome addition to the limited number of works which are devoted exclusively to external diseases of the eye. The following list covers the chapter headings of this work.

Chapter I. A Retrospect of Ophthalmology Relating to External Eye Diseases.
Chapter II. Diseases of the Eye-Lids. Chapter III. Affections of the Lacrimal Apparatus. Chapter IV. Diseases of the Orbit. Chapter V. Diseases of the Conjunctiva. Chapter VI. Diseases of the Cornea. Chapter VII. Diseases of the Sclera. Chapter VIII. Diseases of the Iris. Chapter IX. Diseases of the Ciliary Body. Chapter X. Glaucoma. Chapter XI. Diseases of the Crystalline Lens. Chapter XII. Diseases of the External Muscles of the Eye. Chapter XIII. Hygiene of the Eyes. Chapter XIV. History Taking and Case Records. Chapter XV. Remedies Used in Treatment of External Diseases of the Eye.

While the author states in his preface that the work is limited to those diseases in which a tentative diagnosis can be made without the ophthalmoscope, it is rather difficult to conceive of diseases of the ciliary body, glaucoma and cataract, as external diseases of the eye. In the chapter on diseases of the eye-lids the author has included material which covers not only those conditions seen in this country, but those seen in some of the tropical countries as well.

The illustrations are reproduced both from clinical cases and also from wax models, and as a rule are most excellent, although a few such as pemphigus of the lids require considerable imagination to be able to recognize anything resembling this condition. In a work containing so many illustrations where the visual appearance is the leading point in diagnosis, it is regrettable that stereopticon pictures were not used so that the reader could get, not only a surface appearance, but also depth values as well. Upon the whole, however, the book is to be recommended for both the specialist and the general practitioner.

C. A. C.

COLLEGE NEWS NOTES

Acknowledgment is made of the following gifts to the College Library of publications by members

Dr M B Marcellus (Fellow), Palo Alto, Calif —1 reprint,
Dr W R Riley (Fellow), Battle Creek, Mich —3 reprints,
Dr Hyman I Goldstem (Associate), Camden, N J —1 reprint,
Dr Cullen Ward Irish (Associate), Los Angeles, Calif —1 reprint

Dr Jonathan C Meakins (Fellow and President), Montreal, Canada, was elected President-Elect of the Canadian Medical Association at its annual meeting in Calgary, Alta, June 18 to 22

At the Cleveland Session of the American Medical Association, the Section on Gastro-Enterology and Proctology elected the following Fellows to office

Dr Ernest H Gaither, Baltimore, Md —*Vice-Chairman*
Dr Henry L Bockus, Philadelphia, Pa —*Secretary*
Dr Albert F R Andresen, Brooklyn, N Y —*Member, Executive Committee*

The American Board of Gastro-Enterology, recently organized at Cleveland, elected the following officers

Dr Albert F R Andresen (Fellow), Brooklyn, N Y —*President*
Dr Franklin W White (Fellow), Boston, Mass —*Vice-President*
Dr Ernest H Gaither (Fellow), Baltimore, Md —*Secretary*
Dr Frank Smithies (Master), Chicago, Ill —*Treasurer*

The following were elected additional members of the Board of Regents

Dr George W Eusterman (Fellow), Rochester, Minn
Dr Henry L Bockus (Fellow), Philadelphia, Pa
Dr Sidney K Simon (Fellow), New Orleans, La
Dr Adolph Sachs (Fellow), Omaha, Nebr

At a meeting of the Board of Directors of the Jewish Hospital, Philadelphia, on June 11, Dr Mitchell Bernstein (Fellow) was elected Senior Attending Physician, beginning July 1

Dr Bernstein was elected President on June 5 of the Alumni Association of the Philadelphia College of Pharmacy and Science, from which institution he graduated in 1909, and where he is a member of the Board of Trustees

Dr John Favill (Fellow), Chicago, Ill, has been promoted to the rank of Clinical Professor of Neurology at the Rush Medical College of the University of Chicago

Dr James E Paullin (Fellow), Atlanta, Ga, was made President-Elect of the Medical Association of Georgia at its last annual meeting at Augusta, May 11

Dr Allen H Bunce (Fellow), Atlanta, Ga, was reelected Secretary

Dr Julius H Hess (Fellow) Chicago, Ill, was elected President of the Chicago Medical Society at its last annual meeting, June 19

A public reception was tendered by the Des Moines Chamber of Commerce to Dr Walter L Bierring (Fellow), on June 22, in recognition of his induction into the Presidency of the American Medical Association

Dr William H Robey (Fellow), Boston, Mass, was reelected President of the Massachusetts Medical Society, June 5, at its annual meeting in Worcester

OBITUARIES

JAMES EDWIN HOUGHTON, LIEUTENANT COMMANDER, MEDICAL CORPS, UNITED STATES NAVY

James Edwin Houghton, Lieutenant Commander, Medical Corps, United States Navy, died suddenly at Washington, D C, on May 3, 1934

Dr Houghton was born at Northumberland, Pennsylvania, August 11, 1891 He graduated in 1917 from the Medical School of George Washington University, Washington, D C, and at once entered the Medical Corps of the Navy During the war he served with a laboratory unit Subsequently his service was at sea and in San Domingo and on the Asiatic Station, as well as shore duty in the United States While serving at the U S Naval Hospital at Philadelphia, he was lecturer on tropical medicine at Jefferson Medical College At the time of his death he was Director of Laboratories at the U S Naval Medical School, Washington, D C, and Professor of Tropical Medicine there He had been tentatively selected as the representative from the Medical Corps of the Navy to serve at the Gorgas Memorial Institute of Tropical and Preventive Medicine in Panama He was one of the outstanding bacteriologists of the Navy, as well as a leading expert in tropical medicine He had published a number of professional papers, and had done important work on infectious mononucleosis He had done much work on the technic of the Kahn test and was instrumental in having it adopted as the commonly used test of the Navy Dr Houghton leaves a wife and two children He was made a Fellow of the American College of Physicians in 1926 He was a member of Sigma Chi Fraternity

The loss of so brilliant and promising an officer is deeply deplored by the entire Medical Corps

ADMIRAL PERCEVAL S ROSSITER, M D, F A C P,
Surgeon General, U S Navy

DR JOHN PETER ZOHLN

Dr John P Zohlen, aged 48, a resident of Sheboygan, Wisconsin, died on June 2, 1934, of agranulocytosis, after an illness of four days

Dr Zohlen was born in Germany on September 5, 1886 In his pre-medical training he took his degrees, Bachelor of Arts and Master of Arts, at St Lawrence College, Mt Calvary, graduating in 1909 He attended St Louis University School of Medicine for two years Then he transferred to Marquette University Medical School from which he graduated in 1913 He served an internship at the Milwaukee County Hospital, and became a member of the American College of Physicians in 1930 His specialty was gastro-enterology

At the time of his death he was President of the Sheboygan County Medical Society, and of the Sheboygan Clinic

OTTO A FIEDLER, M D , F A C P ,
Sheboygan, Wis

DR MORRIS HIRSCH KAHN

Dr Morris Hirsch Kahn (Fellow), Fieldston, New York, N Y, died, July 13, at Mount Sinai Hospital, aged 45 years. Dr Kahn, a heart specialist, retired from practice about three years ago because of a heart ailment. He was born at Shklov, Russia, in 1889, came to the United States in his boyhood and attended Cornell University Medical School from which he graduated in 1909. He received the degree of Master of Arts from his alma mater in 1922. He interned at Mount Sinai Hospital, and had been connected with this institution for many years, successively as house physician, resident physician, chief of the clinic for internal medicine and chief of the cardiac clinic. In 1920, he became cardiologist of the Beth Israel Hospital which appointment he held until the time of his retirement.

Dr Kahn was a member of the New York Academy of Medicine, Society for Experimental Biology and Medicine, New York County Medical Society, Eastern Medical Society, New York State Medical Society and the American Medical Association. He was elected a Fellow of the American College of Physicians on December 30, 1926.

He contributed many scientific articles to leading medical journals, including the ANNALS OF INTERNAL MEDICINE.

ROBERT A COOKE, M D , F A C P ,
Governor for Eastern New York

PULMONARY TUBERCULOSIS AS A PART OF A SYSTEMIC INFECTION (HEMATOGENOUS PULMONARY TUBERCULOSIS) ¹

By JAMES ALEXANDER MILLER, A M., M D., F A C P., *New York, N Y*

INTRODUCTION

It is my belief that among general practitioners of medicine pulmonary tuberculosis is usually regarded as a local disease of the lung, produced by the inhalation of tubercle bacilli, and that their ideas of hematogenous tuberculosis are restricted to that form of the disease which we recognize as general miliary tuberculosis

In the light of modern knowledge these are limited and crude concepts of this disease, which greatly hamper our proper appreciation of many important problems concerning its etiology, pathogenesis, clinical manifestations, prevention and treatment

It is my present purpose to review the evidence demonstrating that pulmonary tuberculosis is very frequently a part of a systemic infection, in the hope that this may help to clarify our ideas of this important subject

One of the important objects to be obtained from such a review would be the appreciation of the relationship between first infection with tuberculosis, which usually occurs in early life, and the serious forms of pulmonary tuberculosis which as a rule occur in adult life. In doing so, we will also have occasion to consider the possible desirability of modifying the classifications of pulmonary tuberculosis now in general use in this country

HISTORICAL REVIEW

When Koch first discovered the tubercle bacillus he believed that phthisis was the direct result of a first infection of the lungs with tubercle bacilli. This continued to be the general concept up to the early part of the present century, and Cornet's ¹ handbook on tuberculosis, published in 1904, which was recognized as authority at that time, expresses this view. But it is significant that in this same year of 1904 von Behring ² announced his famous dictum "Adult phthisis is the last tune of a cradle song." But even before that, Petruschky ³ and Hamburger ⁴ had thought of tuberculosis

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934
From the Tuberculosis Division of Bellevue Hospital

as a chronic smouldering infection, and Hamburger particularly, as a pediatrician, classified his cases into early and late forms of the disease. Following the rediscovery and the appreciation of the significance of the primary complex by Albrecht⁵ and particularly by Ghon⁶ in 1912, Ranke⁷ in 1916 built up a very imposing structure about the three-stage evolution of tuberculosis, based upon the theory of blood stream dissemination modified by his ideas of the various states of allergy. Ranke was the first definitely to clarify the idea of phthisis as a final phase of a systemic tuberculous disease which has become localized in the organs, particularly the lungs. In the meantime Maimorek⁸ had demonstrated that tubercle bacilli reach the blood stream within a few hours after the first infection, and Liebermeister⁹ had proved conclusively that bacillemia frequently occurs in tuberculous patients. In recent years Lowenstein¹⁰ has made extravagant claims of the demonstration of tubercle bacilli in the blood, which have not been corroborated by other workers. But the conservative opinion of Wilson¹¹ that bacillemia occurs in about 5 per cent of all patients, and as a transitory phenomenon perhaps much more frequently, is becoming more and more generally accepted.

It is interesting to note that French clinicians in general have always leaned to the idea of pulmonary tuberculosis as a part of a systemic infection. Landouzy¹² coined the term "typho-bacillose" and arrived at his conclusion as to the tuberculous origin of idiopathic pleural effusions because of this point of view. Bard¹³ and Piéry¹⁴ built up a most admirable classification of pulmonary tuberculosis upon this basis, and the more modern phthisiologists such as Rist,¹⁵ Sergent,¹⁶ Bernard,¹⁷ Bezançon¹⁸ all assume that pulmonary tuberculosis frequently represents the extension of a systemic infection to the lungs.

In England, Wingfield¹⁹ has recently offered some very keen observations in support of the concept of the hematogenous origin and evolution of many cases of phthisis.

It is, however, from Germany that the chief recent additions to our knowledge have come. Beginning with Koch, followed by Orth,²⁰ Roemer²¹ and many other experimenters, the idea that phthisis was due to a reinfection rather than to a primary infection was gradually developed. But while the possibility that this reinfection was endogenous was recognized, under the influence of Aschoff²² there was gradually built up the strongly entrenched theory that pulmonary phthisis is due to a new exogenous infection entirely independent of the first infection. The influence of Aschoff and his associates has been very great, and since his visit to this country his ideas have largely dominated American medical thought concerning the pathogenesis of phthisis.

But in the past 10 or 15 years, pathologists and clinicians alike in Germany have been very definitely swinging around to a critical attitude toward Aschoff's ideas. Redeker²³ Loeschcke,²⁴ Duken,²⁵ Schurmann,²⁶ Pagel,²⁷ Rudel,²⁸ and Neumann²⁹ in Vienna all have been stressing patho-

logical and clinical evidence in favor of the close relationship between the first infection and the phthisis which results so many years later

Thus, the issue is drawn between the advocates of exogenous reinfection as the cause of phthisis and those that believe in the endogenous sources of such reinfection

It should be emphasized, however, that no one doubts that exogenous reinfection occurs and is probably quite frequent. On the other hand, it is becoming more and more the accepted idea that the endogenous sources of reinfection have been improperly relegated to the background and are of very marked, if not indeed of predominant, importance

PATHOGENESIS OF TUBERCULOSIS

Primary Infection The primary infection with tuberculosis occurs usually in the lungs, but occasionally elsewhere in the body, particularly the intestinal tract. The original lesion which is produced is usually slight and most frequently is unaccompanied by symptoms. Sometimes, however, it is quite extensive and accompanied by acute symptoms. Associated with the lung lesion there is invariably an accompanying lesion of the neighboring lymph nodes, which in the case of the lungs are the tracheobronchial group. As a rule, these two conjoined lesions become rather quickly quiescent and tend to become calcified, in which phase they are ordinarily recognized either by the roentgenogram during life or by postmortem examination. These two conjoined primary lesions in the lungs and lymph nodes have received the designation of the primary complex.

After this first infection occurs there is a changed reaction in all of the tissues of the body toward tuberculo-protein, which gives rise to the well known sensitization to tuberculin and which definitely changes and tends to localize the tissue reaction to any secondary tuberculous infection which may occur whether from without, which is termed exogenous reinfection, or by dissemination from the original lesion, which is termed endogenous reinfection.

The course of the primary infection itself is variable. The disease may spread acutely from this first infection and rapidly cause death, particularly in young children. Most commonly, however, the lesions subside and become calcified and give no symptoms.

In a considerable number of cases, after a long period of quiescence these lesions which are caseating and partly calcified may discharge tubercle bacilli into the blood stream in varying amounts and at varying intervals. This discharge of bacilli occurs particularly from the lymph nodes. We know that actual pathological healing of these lymph node lesions is very uncertain, even when they appear perfectly calcified they may contain virulent bacilli which may be discharged into the blood. It is from this source that the various forms of hematogenous tuberculosis occur, including certain forms of pulmonary tuberculosis which will be our chief concern in this paper.

Post-Primary Disseminations The discharges of tubercle bacilli from the original primary lesions may occur early or late, often many years after the first infection. In many cases they do not produce disease, under such circumstances it is termed that this secondary infection does not "take." In numerous other cases, however, lesions are formed, which are termed the lesions of post-primary dissemination.

The fact that all of the tissues of the body have become allergic because of the first infection, tends to produce a local reaction wherever these disseminated bacilli may lodge, which tends to localize these lesions. This allergic reaction is a specific one and belongs to the group of reactions which are included under the general term of immunity reactions, but does not produce immunity in the sense of protection against reinfection.

In addition to this allergic change each individual has his or her own constitutional reaction to the tubercle bacillus. This constitutional reaction may be one of great susceptibility or of marked resistance, with all intermediate stages, it may be inherited, it may be racial, it may be strictly individual, and in every individual it is subject to considerable variations during his lifetime, depending upon various general factors many of which are little understood but some of which are connected with such generally recognized conditions as intercurrent or debilitating disease, unfavorable social environment, imperfect nutrition and the like.

The effect produced therefore by dissemination of tubercle bacilli may vary greatly according to the dosage and the virulence of the bacilli, but particularly according to the resistance of the tissues at the time, as affected by the specific and constitutional factors above described.

In the great majority of cases the number of bacilli discharged into the blood is small, the reactions are slight, and the lesions and symptoms produced from them are unnoticed. If a large number of bacilli is discharged at one time, we have an acute general miliary tuberculosis.

In other cases we have fairly severe lesions, with symptoms depending upon the severity and the localization of the lesions. These bacilli may, of course, reach any organ of the body, but the lungs are almost universally reached by this dissemination, because of the vast capillary network of the lungs which acts as a screen for any foreign matter passing through the blood stream. When we have local tuberculous lesions in organs of the body which are not accessible to outside infection, such as the bones, kidneys, lymph nodes, etc., we have no escape from the conclusion that they occurred from blood stream dissemination. In the case of the lungs, however, we have usually thought of these post-primary lesions as being due to exogenous reinfection from the inhalation of tubercle bacilli. That they are very frequently not so produced, but rather come from the blood stream dissemination, just as do these other extrapulmonary lesions, is a concept which is now generally accepted, and our problem is, to attempt to recognize these lesions as such, because they differ very materially in behavior from those due to exogenous reinfections, and because this origin of pulmonary

tuberculosis from the blood stream very materially affects our thinking concerning the incidence and dangers of reinfection of the lungs from the outside. It also adds great importance and significance to the presence and character of the original lesions from which these disseminations occur.

The Character and Evolution of Hematogenous Lung Lesions As a rule, the number of disseminated tubercle bacilli is small, and lodging as they do in the interstitial tissues of the lungs rather than in the walls of the air passages, the symptoms produced are usually systemic at first rather than local. The dose of infection being small, the lesions consequently are small, are productive rather than exudative in character and in general they tend to run a benign course. Coming as they do from infection through the blood stream, these lesions are apt to be bilateral and may lodge in any portion of the lungs but are particularly prone to persist and develop in the cortical areas of the upper lobes, while they tend to absorb from other parts of the lungs. In the majority of the cases they tend to become fibrotic and calcified and are usually recognized in this form by the roentgenogram when there has been no history of obvious lung disease. As these hematogenous disseminations are apt to occur in crops, we may see the evidence of these successive disseminations in the lungs as lesions of varying size and apparently of varying age. At any time, however, during this process a more acute infection may occur, and even to the point of an acute overwhelming generalized tuberculosis which is particularly apt to occur where the lodgment has been in the walls of the blood or lymph vessels, thus making discharge of large quantities of tubercle bacilli an easy possibility.

As the same blood stream infection may reach any organ of the body, these lung lesions are frequently associated with localized tuberculosis in some other organ, and it may be this extrapulmonary tuberculosis which is first recognized clinically. In the overwhelming majority of such cases, however, this is associated with lung lesions also.

In some cases the hematogenous lesions in the lungs and other organs may develop in a protracted but at the same time progressive manner, less acutely than in the case of acute generalized tuberculosis but at the same time in the course of several months producing a widely disseminated tuberculosis in many organs of the body, resulting in death.

In many more cases, however, the lung lesions with periods of quiescence become intermittently active and tend eventually to involve and to break through into the air passages, especially the smaller bronchi. When this occurs, we have a distinct change in the character and evolution of the disease which then progresses just as though the process had originated in the walls of the bronchi as is the case when the infection is due to the inhalation of bacilli. It is then that pulmonary symptoms such as cough, expectoration, hemoptysis, etc., occur. This form of tuberculosis of the lungs is termed bronchopulmonary phthisis.

Bronchopulmonary Phthisis In a considerable number of cases bronchopulmonary phthisis is undoubtedly in association with exposure and

exogenous reinfection in an individual who has already become allergic because of his primary infection. A conspicuous example of such lesions is the ordinary infraclavicular infiltration with which we are all familiar and which is usually described under the term adult form of pulmonary tuberculosis. Here again the upper lobe localization is characteristic, but they are apt, at first at least, to be unilateral and they are not apt to be associated with extrapulmonary lesions in organs not accessible to the outside. When well developed, however, there is little to distinguish such exogenous bronchopulmonary phthisis from the endogenous form which we have already considered.

When once established, this localized form of tuberculosis called bronchopulmonary phthisis no longer tends to spread by the blood stream. Such dissemination may occasionally occur, but is rare. The usual extension of this form of tuberculosis is by what is termed intracanalicular spread, that is, by the passage of tubercle bacilli through the normal canals of the body to other organs or to other portions of the same organ. In the case of the lungs this is by the bronchi and is termed bronchogenic spread, and is the usual method of progression of phthisis from the apex downward in the same lung or over into the opposite lung. This spread is often accelerated by favoring circumstances such as hemorrhage. It is by this same route that the larynx becomes infected through the expectoration of sputum, and it is also by the same method of intracanalicular spread that secondary intestinal tuberculosis occurs, due to contact with infected sputum.

When the localized organic tuberculosis is in an organ of the genito-urinary tract, such as the kidney, again spread of the infection occurs through the normal canals downward to the bladder, or if it starts in the epididymis, upward through the genito-urinary canal to the bladder and to the kidney.

This tendency of bronchopulmonary phthisis to extend by this method of intracanalicular spread makes possible the formation of very considerable lesions within a short time and rapid spread of the disease, and changes the general course of the disease when one compares it with the much slower and finer dissemination of infection which occurs through the hematogenous route.

In general, in every case of tuberculosis, whether it has developed hematogenously or intracanalicularly, the course of the disease is apt to be intermittent, with periods of exacerbation and remission, which correspond to these recurrent discharges of infection.

The course also varies with the amount of such discharge, with the constitutional resistance and the specific allergy of the tissues, both of which vary in different individuals and in the same individual at different times, and also is influenced by certain accidental factors such as the occurrence of hemorrhage or the discharge of large quantities of tubercle bacilli at one time, either into the blood stream in the case of hematogenous dissemination or into the bronchi in the case of bronchogenic dissemination.

An important fact to recognize is that the clinical manifestations of tuberculosis are practically invariably those of a secondary infection, and that consequently primary infection does not afford a true degree of protection, certainly nothing that we can call a true acquired immunity. It is also important to bear in mind that once there is a primary tuberculous focus in the lymph nodes or in any other organ of the body, the absolute healing of such lesions is a matter of great uncertainty, and that consequently the old dictum, "once tuberculous, always tuberculous," is near to the truth, and inasmuch as these slight lesions from which hematogenous forms of tuberculosis arise are so small and so often give no symptoms, the hazards which attend their existence should be more thoroughly recognized, and if a considerable proportion of disabling or fatal phthisis arises from this source then the measures which may be taken to prevent the occurrence of such active disease from them should be thoroughly understood.

CLINICAL FORMS OF HEMATOGENOUS PULMONARY TUBERCULOSIS

Diagnosis The recognition of the hematogenous origin of acute general miliary tuberculosis and of the disseminated protracted progressive forms of the disease, is easy. At the other end of the scale, after bronchopulmonary phthisis has occurred the decision as to whether this occurred from the hematogenous or the exogenous route is extremely difficult, if not indeed impossible.

In other cases the association of a definite type of pulmonary lesion recognized during life, with an extrapulmonary tuberculosis may lead to the inference that both lesions are from the same hematogenous source.

In certain other cases the occurrence of these localized lung lesions, even though apparently healed as they may appear with the roentgen-ray, associated with recurrent mild systemic disturbances of general health, such as chronic poor nutrition, irregular slight rises of temperature, digestive disturbances, undue malaise and fatigability, may lead to the suspicion of a tuberculous infection mild in degree and possibly hematogenous in source as the cause of such symptoms.

In the lungs, these hematogenous lesions at first not being open to the air passages, may produce no pulmonary symptoms whatever. In other cases the first chest manifestation may be an acute pleural effusion, which is probably very frequently of hematogenous origin. In other cases a small calcified nodule may ulcerate a small vessel, causing a slight hemoptysis. Careful study of the roentgenological evidences of tuberculosis will show that these interstitial lung lesions before bronchopulmonary phthisis has developed have a fairly characteristic appearance. They are usually small and multiple and usually bilateral, with a definite tendency to localization in the upper lobes and to marked calcification. In other cases there are very numerous granular densities throughout the lung fields, closely simulating the appearance of a general miliary tuberculosis, but without

any of the acute systemic symptoms of this disease. Such miliary lesions often come in crops, frequently disappear in a period of a few weeks or months, and may reappear at varying intervals, associated with a varying degree of constitutional disturbance, often very slight.

In still other cases there is a tendency for the infection to travel from the interstitial tissues of the lungs along the lymphatics, giving a strand-like roentgen-ray appearance which has been likened to the meshes of a veil. In other cases the lodgment of the tubercle bacilli may cause rapid caseation, with the formation of small cavities with the characteristic punched-out appearance, very thin walls and surrounded by apparently normal tissue, quite different from the appearance of the ordinary cavity of fibrocaseating phthisis. Such cavities often appear and disappear very rapidly, changing their shape easily, and sometimes may develop into ordinary bronchopulmonary phthisis.

The recognition of these clinical forms of so-called hematogenous pulmonary tuberculosis is largely attained by skilful study of the roentgenogram. Naturally, this leaves such interpretation open to differences of opinion and has led to a very considerable discussion as to the actual scientific basis upon which the diagnosis of these hematogenous forms rests. But, in general, as one comes to study these cases and thinks of them in terms of a lack of local symptoms in the early stages and the frequent association with tuberculous lesions in other parts of the body of undoubtedly hematogenous origin, one gets gradually to recognize a group of pulmonary cases which one believes to be of hematogenous origin.

Moreover, frequently in these cases the roentgen-ray will definitely show the remains of the primary complex both in the lungs and particularly in the tracheobronchial lymph nodes, and in the case of the latter often associated with large densities with more or less calcified deposits, but also showing the possibility of caseating lesions still existent.

Classification. Our review of the pathological and clinical manifestations of tuberculosis will now enable us to consider a question raised earlier, namely, the problem of classification.

We have seen that the ordinary disabling pulmonary tuberculosis is bronchopulmonary phthisis, and everybody realizes that this is due to a reinfection, whether this be exogenous or endogenous, and also everybody realizes that this form of phthisis is much more common in young adult life than it is among children. On the other hand, it appears obvious that there is at least a strong probability that many cases of bronchopulmonary phthisis owe their origin to previous lesions which have been disseminated from the primary infection which occurred in childhood, and that in such cases at least the development of the bronchopulmonary phthisis in adult life should be correlated with the earlier manifestations of the same disease. It is also important to remember that the so-called adult type of phthisis really occurs quite frequently in childhood.

But even more important is it to remember that the childhood type of tuberculosis is recognizable in a very large number of adult individuals who have not as yet at least developed bronchopulmonary phthisis, and that also not infrequently in adults the forms of disseminated tuberculosis which we recognize as more common in children, may occur

The question is therefore raised as to whether it is desirable to bring in the question of age distribution in any system of classification, and whether it would not be more helpful to the understanding of the problems involved if we thought rather of the underlying pathological processes and pathogenetic principles

Considering the problem in this way one would rather come to recognize two general clinical forms of pulmonary tuberculosis (1) The form in which the infection travels by the lymph and blood stream, producing lesions which remain closed in the interstitial structures of various organs of the body. It is recognized that while in this closed form frequently few or no symptoms are exhibited and all that we could recognize is the evidence of old quiescent lesions, on the other hand mild constitutional symptoms do occur in such cases, either because of fresh blood stream disseminations or because of lighting-up of mild activity in preexisting lesions

Now, it is in this form of tuberculosis that the lymph nodes are particularly involved, and that as far as the lungs are concerned there are very few if any focal symptoms, and it is this form which is often associated with lesions in extrapulmonary organs

While this is the usual form of tuberculosis seen in childhood, it must be remembered that the lesions in either a quiescent or an obsolete state persist throughout life and can be recognized, so that careful examination of many adults who have no symptoms will definitely demonstrate the presence of this so-called childhood form of tuberculosis

Bard¹⁷ and Piéry¹⁴ devised a very detailed classification of the pulmonary forms of this type of tuberculosis, and Neumann²⁰ has adopted and amplified this classification for clinical use into a very complex system. While the various forms which these authors describe can be recognized after careful study, their very complexity makes them cumbersome and detracts from the usefulness of such classification.*

I have found it simpler and more practicable to include all of these forms under the general designation of lymphohematogenous tuberculosis, while recognizing the fact that this type of the disease develops many various phases during its evolution

(2) In very strong contrast to this type of tuberculosis we have the bronchopulmonary phthisis. Here, we have serious, often disabling or fatal disease with usually definite pulmonary symptoms and with spread of the disease not by the blood stream but through the canal system of the body, particularly in the case of the lungs through the bronchi. This type

*I have described the main forms included in this classification in a previous communication (Am Rev Tuberc, May, 1934)

of disease, as already stated, may occur in childhood but usually does not develop until young adult life. But inasmuch as we have already seen that the recognizable childhood types persist into adult life, the question which arises is: Is the bronchopulmonary phthisis due to an entirely new infection from the outside, or is it due to a flaring-up of these old long-standing childhood lesions? If, as it seems to be true, it often may be due to such lighting-up of childhood lesions, the disease is therefore a continuous one and should be thought of rather in terms of whether the infection is confined in the closed tissues of the body or whether it has gained access to the external mucous membrane surfaces of the bronchi. It is the latter condition which converts it into a serious, disabling disease.

It is a very important and interesting problem not yet solved as to why such latent tuberculosis does not develop more frequently into open phthisis during childhood, and more important still as to why in some cases in adults it so develops into open phthisis and in so many other cases it does not. The correct solution of this problem would undoubtedly lead to the prevention of many cases of pulmonary phthisis which now occur.

The National Tuberculosis Association classification of pulmonary tuberculosis applies in the main to the various stages of this form of tuberculosis, namely, bronchopulmonary phthisis. What we are designating as lymphohematogenous tuberculosis is classified in the American system as the childhood type of pulmonary tuberculosis.

While the National Association classification has a wide field of usefulness, it has the disadvantage of all fixed systems in that it lacks flexibility and encourages the concept of pulmonary tuberculosis as a static process. As a matter of fact, the evolution of tuberculosis is a moving or dynamic process subject to frequent change. The minimal case of today, for example, may be a III C case tomorrow, following a hemorrhage with widespread bronchogenic dissemination of new lesions and with marked constitutional disturbances.

Without discarding the use of this classification entirely, I have found the less static division of cases into (a) the lymphohematogenous type with closed interstitial lesions and extension through the lymph and blood stream, and (b) the bronchopulmonary phthisis type, with extension through the air passages, most helpful in the understanding of the various phases of this kaleidoscopic disease. I believe that the classification into childhood and adult types may be actually misleading.

Prognosis It is obvious from our discussion of the clinical course of these cases of hematogenous tuberculosis that the prognosis in any individual case will depend upon many factors and would be very variable. The important thing would appear to be to recognize the fact that we are dealing with the form of tuberculosis which while it remains in this closed form is apt to run a benign course, with very few constitutional symptoms which usually respond satisfactorily and promptly to rest treatment.

On the other hand, it is important to realize that many of these cases have no symptoms at all during life, but in some of these apparently well people reactivation of their lesions will occur and disabling phthisis result. Once recognized, therefore, this form of tuberculosis should never be entirely dismissed as a negligible condition.

After these pulmonary lesions have gone over into bronchopulmonary phthisis, which as we have seen they frequently do, the prognosis in such cases presents all of the variations and possible seriousness which is well recognized in this form of the disease. Most frequently it is the determination of whether we are dealing with the closed lymphohematogenous form, or the open bronchopulmonary form, that is important from the standpoint of prognosis and of treatment.

Treatment As long as these hematogenous lung lesions remain localized and in the quiescent stage they may need little or no treatment, but the danger of exacerbation being what it is, their recognition calls for the institution of a program of repeated examination and supervision to provide a protective environment which would prevent them from becoming active disease and which also may have the effect of preventing further disseminations of bacilli from the original focus.

The physician recognizing such cases would not put them in a sanatorium, but would have them report regularly for check-up of the general condition and particularly for repeated roentgenological examination. Every effort should be made to keep the state of nutrition of such a patient good, to avoid over-exertion and stress of every sort.

We are all familiar with the results of such a program for children who have tuberculous tracheobronchial lymph nodes and who respond positively to the tuberculin test. They need more rest than the normal child, they are restricted as to hard exercise, they are given more out-of-door life, special attention is given to their diet and the improvement of their nutrition, with the addition of vitamins, particularly of vitamin D in the form of cod liver oil or some of its derivatives. It is in a similar way that artificial or natural heliotherapy may exert beneficial effects in such cases.

What we now have to recognize is that this type of disease is not confined to children, that the danger of development of hematogenous forms lasts into adult life, that the safeguard and the protection which we well recognize is useful for certain children, is equally important for many adults. If cases of this sort are recognized as possible sources of active tuberculosis, there can be no doubt that many of the advanced forms of the disease, including many cases of progressive bronchopulmonary phthisis, could be prevented.

According to our modern ideas, the treatment of bronchopulmonary phthisis after it occurs, whether from endogenous or exogenous reinfection, is the prevention of bronchogenic spread, particularly after caseation and cavity formation have occurred, and this bronchogenic spread we now know can be most satisfactorily and quickly prevented by bed rest aided by suitable

mechanical means, in which term we include the various types of collapse therapy such as artificial pneumothorax and some of the more radical forms of surgical treatment

In general, this form of mechanical treatment is not applicable to the usual forms of hematogenous pulmonary tuberculosis before they have gone over into the stage of bronchopulmonary phthisis

The slow evolution which occurs in many forms of hematogenous tuberculosis of the lungs suggests that it is in this form of the disease that possibly changes in tissue reaction might be artificially produced by some form of specific therapy. This is not by any means a generally accepted idea, but the fact that even the rather generally discredited tuberculin treatment still does appear in certain types of cases to have beneficial results, and that it is still widely used in such definitely hematogenous forms of the disease as occur in the eye or to a less extent in the lymph nodes, leads one to raise the question whether if we apply our mechanical methods of treatment to bronchopulmonary phthisis and limit our efforts in experimentation with specific therapy to the hematogenous forms, we may not be able to look forward to the future development of more successful specific therapy. Not a few authorities, of whom Neumann is perhaps an outstanding example, are using tuberculin widely, basing its use on just such principles. The idea at least gives us a basis of some hope for the future.

Prevention The prevention of disabling lung tuberculosis is in the main the question of the prevention of bronchopulmonary phthisis. This means the prevention of secondary infections, those from the outside may be guarded against by avoiding close association with active sources of infection, those from the inside may be averted by protective measures tending to keep locked-up the infections that already exist, and tending also to keep the general and specific resistance of the individual such that the bacilli which are disseminated do not produce serious forms of the disease.

That this can be done by the program of supervision and protective environment has already been widely demonstrated in the case of children. The extension of this program to similar cases in adults will certainly prevent the development of many cases of progressive tuberculosis which now occur.

The absolute prevention of tuberculosis would appear to depend upon the prevention of the primary infection. That this is not a utopian idea is evidenced by the fact that an increasing number of adults grow up without tuberculous infection, as instanced by the increasing age incidence at which positive tuberculin reactions appear in various groups of the population. The doctrine that the primary infection really protects in some way from tuberculosis must probably be profoundly modified. That this primary infection changes the reaction of the individual to secondary infection is undoubted, but this changed reaction tends toward a more acute form of the disease, and in that sense the individual may die from the effects of his own immunity. This whole problem of the relative protection and relative

danger which lie in the first infection is one of profound scientific and practical interest, which is not by any means completely solved

SUMMARY

1 The usually recognized clinical form of pulmonary tuberculosis is bronchopulmonary phthisis. This form of the disease is always due to a secondary infection, which may be exogenous, but is very frequently endogenous from the smoldering primary focus or from one of its satellites arising in the form of early or late post-primary hematogenous dissemination.

2 Many other forms of pulmonary tuberculosis recognizable by the roentgenological as well as by the clinical features and course, are due to such hematogenous disseminations. Such processes are usually localized in extent and benign in character, and very frequently the individual with them may go through life with but few symptoms.

3 While many of these processes appear, and may indeed be, for long periods apparently obsolescent, and need then no active treatment, it should yet be remembered that such lesions have potentialities for development, at any time, into serious and fatal forms of the disease. Such cases, therefore, should be regularly examined and the general course of their life regulated and supervised. The development of some sort of specific therapy in the control of this type of lesion is also a possibility of the future.

4 Extrapulmonary tuberculosis—excepting intestinal and laryngeal—is practically always of hematogenous origin, and when recognized should invariably lead to the investigation of the lungs which will very frequently also be found involved in the process.

5 Extension and coalescence of the lesions in pulmonary tuberculosis take place for the most part by intracanalicular spread. Bronchopulmonary phthisis is thus produced, in which mechanical treatment plays its chief rôle. Hematogenous dissemination occurs but infrequently as a complication of manifest bronchopulmonary phthisis. Consequently, such acute forms as miliary tuberculosis are rarely seen in this class of case.

6 The division of pulmonary tuberculosis into two broad types, namely, lymphohematogenous and bronchopulmonary, affords a better conception of the dynamic character of the evolution of the disease than does the rigid adherence to fixed or static systems of classification.

The term childhood type of tuberculosis is misleading for the reason that so often the characteristic evidences of this type persist into adult life when they may develop into more serious forms of the disease.

7 The recognition of the importance of these principles and especially of the rôle of systemic infection, leads us to a better understanding of many forms of tuberculosis, to a more rational method of treatment adapted to each individual case, and to the possibility of preventing many cases from developing from the milder into the more serious forms of the disease.

THE BLOOD SEDIMENTATION TEST ITS USE AS A ROUTINE, ESPECIALLY IN PULMONARY TUBERCULOSIS¹

By PAUL H. RINGER, A. B., M. D., F. A. C. P., and MARY ROACH,
Asheville, North Carolina

IN 1918 Fåhræus¹ first noted an increase in the sedimentation rate of red cells in citrated blood in pregnant women. At once this was hailed as a new test for pregnancy, but it was soon found to be unreliable in the early months when, of course, its importance was greatest. The test is reliable for pregnancy after the twelfth week if no concurrent infection exists, but by that time its diagnostic value has necessarily been lost. Furthermore, it was soon discovered that acute and chronic infectious processes and malignant new growths had a marked effect upon the sedimentation rate.

TECHNIC EMPLOYED

In this work the technic of Cutler² has been used. In brief it is as follows: "Specially designed sedimentation tubes of 1 c. c. capacity are used, graduated into 50 mm. divisions, with 0 at the 1 c. c. level, each millimeter indicating 0.02 of 1 c. c. One-tenth of 1 c. c. of a 3 per cent sodium citrate solution and 0.9 c. c. of blood, obtained by puncture of a suitable vein, are gently mixed in a 2 c. c. syringe and poured into the sedimentation tube. The position of the sedimenting column of erythrocytes is determined every five minutes for an hour. The observations are recorded on charts that have been designed for the purpose, on which the horizontal lines represent the divisions on the tube and the vertical lines the intervals of time. Graphs are then constructed, which not only show the position of the sedimenting column of erythrocytes at any period of time during the first hour, but also portray the changes in velocity that occur during the process of sedimentation."

Walton³ feels that the sedimentation rate should be corrected to correspond to a standard of 5,000,000 red cells to the cubic millimeter as he finds that the rate is markedly increased in proportion to the degree of anemia present. He cites as an example the rate in a normal individual whose blood was diluted to represent respectively blood containing four, three, two and one million red cells to the cubic millimeter. His table reads as follows:

Normal Individual

| <i>5 Tubes</i> | | <i>Rate in One Hour</i> |
|--------------------|--|-------------------------|
| 5 million R. B. C. | | 1 mm |
| 4 " " | | 6 " |
| 3 " " | | 10.5 " |
| 2 " " | | 20 " |
| 1 " " | | 27.5 " |

* Read at the Chicago meeting of the American College of Physicians, April 18, 1934

This method, from the standpoint of scientific accuracy, is probably the ideal one to use. As a practical clinical procedure, however, it is intricate and time-consuming, while that of Cutler is simple and rapid. Furthermore if, as in all my cases, red counts are made at the same time that the sedimentation rate is estimated, allowance can be made for the various degrees of anemia encountered. The procedure now under consideration is a practical office, bed-side or dispensary test that can be done with a minimum of effort, and in which the human equation does not figure in reading the result.

Again, though the most important methods now are those described by Fåhræus,¹ Linzenmeier,⁴ Gram,⁵ Rourke and Ernestene,⁶ and Cutler,² only Gram, and Rourke and Ernestene (besides Walton³) make any attempt to correct the sedimentation rate for fluctuations in red cell count. This should be fairly good evidence that the majority of workers have found the method here employed clinically satisfactory and trustworthy.

NATURE OF THE REACTION

No definite proof of the cause of increased sedimentation rate has been brought forth, but it is being generally accepted that the phenomenon depends upon the amount of cellular destruction going on in the body. In the ordinary wear and tear of life there is constantly present a process of tissue destruction accompanied by a similar amount of tissue repair. To quote Cutler² "Should the amount of tissue destruction pass beyond the normal, then the stability of the blood is seriously disturbed and the red blood cells settle out quickly from the plasma. Regardless of the disease present, whether it be active pulmonary tuberculosis, malignancy, pelvic inflammatory disease, and acute infections such as typhoid fever, or any disease in which tissue destruction is going on at a greater pace than normal, the rapidity of settling of the red blood cells is in direct proportion to the severity of the disease."

Bortree⁷ says that "Various theories have been propounded to explain the alteration in the rate of sedimentation: changes in electrical potential of the cells, alteration of cell volume or mass, viscosity or chemical variance, etc. Present opinion is that the relative speed of sedimentation of erythrocytes is dependent upon the colloidal chemistry of the blood, and chiefly upon the globulin-fibrinogen ratio. In conditions involving rapid destruction of tissue, there is found in the blood an excess of fibrinogen. In any case where the content of fibrinogen in the blood is above normal, the speed of sedimentation is increased. The greater the increase of fibrinogen content, the more rapid the sedimentation rate, so that the two curves run virtually parallel. However, the sedimentation test is so much simpler than a fibrinogen determination that it is to be preferred in clinical work."

LIMITATIONS OF SEDIMENTATION TEST

The test is absolutely non-specific. It is an index of activity of infection or of malignant growth. It is, however, a valuable and useful prognostic aid and in this connection has been used more particularly in gynecology and in tuberculosis. At times it will act as a "lead," as when a patient is seen with practically negative physical and laboratory examinations but with a high sedimentation rate. One can then be sure that there is some process (other than pregnancy) causing active cellular destruction, and search for the offending cause must be continued. Practically all acute infections are accompanied by an increase in the sedimentation rate, but there is no relationship between the temperature curve and the sedimentation curve, nor is there any relationship between the degree of leukocytosis and the rapidity of sedimentation. (Chart 1)

CHART I

DISEASES GROUPED ACCORDING TO SEDIMENTATION RATES (CUTLER)

With an Abnormal Sedimentation Rate

- 1 Chronic infectious diseases, such as tuberculosis and syphilis
- 2 Acute infectious diseases, such as pneumonia, septicemia, acute endocarditis, the exanthemata and acute bronchitis
- 3 Malignancy
- 4 Localized suppurations, such as pelvic inflammatory disease, suppurative mastoiditis, suppurative sinusitis, empyema of the gall-bladder, bronchiectasis
- 5 Acute intoxication, such as lead and arsenic poisoning
- 6 Certain endocrine disturbances, such as thyroid toxicosis

Influencing the Sedimentation Rate Very Little If At All

- 1 Simple catarrhal inflammations, such as acute catarrhal appendicitis, simple rhinitis and colitis
- 2 Chronic ulcerations of small extent, such as gastric or duodenal ulcer

Not Influencing the Sedimentation Rate

- 1 Functional diseases, such as the various neuroses, and neurasthenia
- 2 Certain nervous diseases, such as dementia precox
- 3 Focal infections, such as abscessed teeth, diseased tonsils and chronic sinusitis
- 4 Metabolic diseases, such as uncomplicated diabetes and essential hypertension
- 5 Allergic diseases, such as asthma and hay fever
- 6 Most skin diseases
- 7 Simple growths, such as fibroma, lipoma and fibromyoma
- 8 Simple cysts
- 9 Chronic valvular disease of the heart

It is generally conceded that in tuberculosis the sedimentation test represents the intensity and degree of activity of the process. Walton³ states that "a normal sedimentation rate has never been found with an *active* tuberculous focus." I cannot agree with this statement, but of course the same definition of "activity" must be employed. The one that I prefer is "Activity is present when the patient is suffering from symptoms, which symptoms are due to tuberculosis." Adopting that as a standard, I have seen many individuals with a normal sedimentation rate who had unquestionable evidences of activity.

It is true that in tuberculosis the sedimentation rate is an excellent guide to progress and most closely parallels radiological changes. If the roentgen-ray findings are equivocal, as they so often are, the nature of the sedimentation test will often determine the direction in which the patient is headed. Roche⁸ uses the sedimentation rate as an index for the beginning of exercise and even in the presence of normal pulse and temperature rates waits until the sedimentation rate is approaching normal before allowing exercise. Again, if a patient is simply not "feeling fit" and yet presents no objective symptoms, a normal sedimentation rate would point toward a nervous etiology rather than an organic one. A rise in the sedimentation rate may precede hemoptysis. Repeated tests are very valuable as the rate will change rapidly for better or for worse. From an economic standpoint, the ease and practical costlessness of the test add to its value.

The sedimentation test is not a substitute for any existing clinical or laboratory procedure but is complementary to them. The test is not infallible, but neither are the majority of laboratory procedures. Very rarely, in less than 1 per cent, a normal rate will be found in the presence of active clinical disease, save in certain cases of tuberculosis as mentioned above.

Types of Graphs (Figure 1)

All authorities recognize four distinct types of graph

- 1 A horizontal or practically horizontal line,
- 2 A diagonal line,
- 3 A diagonal curve,
- 4 A vertical curve

The nearer the line is to horizontal the more normal it is, but thousands of observations have fixed the high normal limit at 8 mm in men and 10 mm in women.

Figure 2 shows the nature of the curves at various months of pregnancy. I was able to obtain these through the courtesy of my colleague, Dr R. A. White, of Asheville.

Figure 3 shows the curves in four widely different conditions coming under my observation, namely,

Cirrhosis of liver—luetic
 Chronic cholecystitis
 Carcinoma of lung
 Empyema—non-tuberculous

Figure 4 is that of a patient who had been wrongly diagnosed as a case of acute fibrinous pleurisy. The clinical picture was not that of pleurisy and the high sedimentation rate pointed to something else. In a few days a perirenal abscess was discovered, evacuated surgically, and recovery set in. The sedimentation rate rose shortly to within practically normal limits.

My work on the sedimentation test in tuberculosis is based on 272

patients, in whom a total of 552 sedimentation rates were made by my technician, Miss Mary Roach, 204 of these patients had diagnosticable tuberculosis, of the remaining 68, there were 51 that were diagnosed as having no definite disease, many of these having requested examination because of relationship to or contact with tuberculous patients. The remaining 17 patients had conditions which are not of sufficient importance to be enumerated in detail in this communication, though certain outstanding ones are mentioned.

Of the 204 having tuberculosis, there were 44, or 21 per cent, in stage 1, 54, or 27 per cent, in stage 2, and 106, or 52 per cent, in stage 3, the classification being that adopted by the National Tuberculosis Association and corresponding to minimal, moderately advanced and far advanced, respectively.

Due perhaps to an innate dislike for long and complicated tables, I have felt that it would be most instructive to cite various typical cases showing the reliability of the sedimentation test as a corroborative and occasionally as a warning factor as to the progress of patients suffering from tuberculosis.

Figure 5 shows the sedimentation rates in a man with a far advanced bilateral tuberculosis in whom any type of pulmonary compression was out of the question because of the anatomical distribution of the lesions. Fifteen months of bed-rest brought about quiescence of the pathological process and corresponding slowing in the sedimentation rate.

Figure 6 shows the improvement in the sedimentation rate in a patient with advanced but stationary lung disease, but with a severe laryngeal tuberculosis. Under treatment by the actual cautery at the hands of Dr. J. B. Greene, of Asheville, marked improvement took place in the laryngeal condition which was faithfully reflected in the change in the sedimentation rate.

Figure 7 is from the records of a most remarkable case—a patient with marked bilateral pulmonary involvement who did badly for three months, a pleural effusion developed on the left side (that of major involvement) and immediately marked clinical improvement set in, which is apparent from the slowing in the sedimentation rate.

The next two cases are in what I term the "warning" class. Figure 8 shows the rate in a patient with minimal physical and radiological signs of disease and clinically symptom-free. The roentgen-ray and physical signs remaining stationary for several months, she was allowed to return to her home in Washington classified as "apparently arrested," despite the fact that the sedimentation rate had remained practically stationary. Within one week of her return she had a profuse hemoptysis which was repeated within three weeks, and resort was had to artificial pneumothorax, as a result of which she is now doing satisfactorily. I believe I was guilty of an error of judgment in allowing the girl to discontinue her cure in the absence of a normal sedimentation rate, though I believe she would have had her hemoptysis just as promptly in Asheville as in Washington.

Figure 9 is that of a patient still under treatment, with an advanced lesion of the left lung with cavity formation. Pneumothorax was successfully induced, but adhesions prevented the closure of a four centimeter cavity. Internal pneumolysis was then successfully attempted by Dr Julian Moore and the cavity was reduced to two centimeters in diameter. This patient is in excellent clinical condition, well up in weight, fever-free, coughing and expectorating far less than before her pneumolysis, but the persistently high sedimentation rate is ominous and I fear that she is headed either for a hemorrhage from the as yet unclosed cavity or, more probably, for a spread of disease in the contralateral lung, which unfortunately is not free of involvement. Time alone will tell the tale, but the sedimentation rate in this patient has caused me to handle her most carefully.

The next four cases illustrate improvement noted in patients subjected to various forms of pulmonary compression.

Figure 10 shows the marked slowing in the sedimentation rate after five weeks of treatment by artificial pneumothorax. The patient, a slip of a girl, had a very active, wholly unilateral process. The results following compression were clinically startling: prompt disappearance of fever, practically total suppression of cough and sputum and corresponding physical betterment. The slowing in the sedimentation rate is certainly striking.

Figure 11 illustrates betterment as evidenced by the sedimentation rate in a patient with an apical cavity in whom artificial pneumothorax could not be induced because of adhesions. A phrenic neurectomy was done by Dr Julian Moore, rendering the patient symptom-free and showing within a month marked slowing in the sedimentation rate.

Figure 12 is from the records of a patient with unilateral cavitation who, after several months of bed-rest with no improvement, was given artificial pneumothorax, but, as so often happens, the cavity was held open by adhesions. An internal pneumolysis was successfully done, again by Dr Moore. Clinical improvement was gradual but steady, as is shown by the four sedimentation rate estimations between February and October, 1933. While the patient still has a pleural effusion, he is clinically well and wholly symptom-free.

Figure 13 shows the rapid improvement in a patient with a far advanced fibro-caseous tuberculosis of one lung. She was definitely on the downgrade when a three-stage paravertebral extrapleural thoracoplasty was begun by Dr W P Herbert about July 15, 1933. Remarkable clinical improvement was brought about, improvement which is borne out by the marked slowing of her sedimentation rate. It must be remembered that within practically four weeks this patient was subjected to three major operations which greatly exhausted her physical resources.

Figure 14 is an interesting one. The patient had a unilateral cavity for which artificial pneumothorax was successfully instituted. Mechanically the procedure was a success. The cavity was closed but the patient did not do well. No spread of disease could be found in the contralateral lung.

Digestion was bad, anorexia ensued, loss of weight resulted and her last state was worse than her first. On July 3, 1933, pneumothorax was abandoned, the air remaining in the pleural cavity aspirated in an effort toward aiding the compressed lung rapidly to reexpand. The patient literally took on a new lease of life. Note the marked change in the sedimentation rate between July 3 and July 28, 1933.

Figure 15 well illustrates the changes in a patient gradually but steadily going downhill over a period of almost 16 months despite the induction of an artificial pneumothorax and the performance of a phrenic neurectomy. This patient has never had enough resistance to go "over the top," a fact which the sedimentation rate emphasizes.

As a result of two years' experience with this test and because of the results obtained as evidenced by the charts shown here, I feel that it is one of real value. I agree with Townsend⁹ that it parallels the severity of the disease. Banyar¹⁰ believes that no tuberculous patient should be discharged until the rate is normal. I am rather in agreement with him, having in mind the girl whose graphs I have shown and who had a hemoptysis within a

week after her return home. From all clinical evidence, this girl should have had a normal sedimentation rate, yet she could never quite obtain one. Walton³ has such an excellent paragraph on the value of the test that so exactly reflects my own conclusions that I cannot refrain from quoting him:

It is a most delicate and sensitive reaction, which reflects very faithfully the state of equilibrium of the blood in relation to any pathological process. It is not specific for any disease, therefore, its uses as a specific diagnostic agent are almost limited to the domain of tuberculosis, where it may be employed in conjunction with a small provocative dose of tuberculin. Used cautiously, however, and as an adjunct to the clinical picture, the sedimentation test, if correctly interpreted, will be found to possess great value, and will often weigh down the scales of differential diagnosis.

In my own experience, based mainly upon cases of pulmonary tuberculosis, I have come to rely greatly upon it, feeling that it reinforces physical, radiological and symptomatic evidence, and frequently presages oncoming evil, or, on the other hand, gives one confidence in the ultimate outcome when clouds loom dark on the clinical horizon.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS *

By RALPH C MATSON, M D , F A C P , F A C S , *Portland, Oregon*

AN analysis of our present knowledge of the advances made in the treatment of pulmonary tuberculosis clearly indicates that rest is the foundation and its development the only important and successful remedial furtherance in the treatment of this disease. Detweiler is credited with being the first to advocate rest as a therapeutic measure, but Joseph H. Pratt points out that Trudeau indorsed it before Detweiler. From a surgical standpoint, the development of rest as a curative method forms the basis of modern phthisiotherapy.

Valuable adjuncts to bed rest are postural rest on the diseased hemithorax and shot-bags placed on the front of the chest when the patient lies in the dorsal position. It is true that these expedients prove sufficient to bring about a recovery in many cases of pulmonary tuberculosis in the early, and even in the moderately advanced, stages. However, if cavities have already formed, the rest regimen is too often a failure because of the frequency of bronchogenic extension of disease to the same and opposite lung, the larynx and gastrointestinal tract.

The importance of closing cavities promptly is gradually being recognized, and valuable time is not wasted so grievously on prolonged sanatorium routine while other vital means could be utilized. The ever present possibility of disease extension is not the only danger to be regarded, for there is also the additional menace to the health of others. We have for an illustration the ambulant cavity case who looks and feels well, except for cough and expectoration. It is self-evident that the sooner the cavity is closed the better—not only for the individual patient, but for those who live and work with him.

The ambulant cavity case as a carrier is strikingly shown by our experience with salesgirls employed in a ladies' specialty shop, where one after the other (numbering six) developed tuberculosis. The source of infection was unquestionably traced to the personnel manager, who eventually presented himself for examination, which disclosed bilateral cavity formation. By his own admission, he had been tuberculous for years.

The unsatisfactory results of prolonged bed and postural rest, and the danger of delayed closure of cavities demand the immediate utilization of other methods of hastening recovery in this type of case. If no signs of improvement are seen after a reasonable trial of bed rest, postural rest and shot-bags, other methods of obtaining the needed relaxation for the lung

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934.

should be employed without further procrastination. The proposed operative procedures are those included under the term "collapse therapy," their basis consisting in providing rest for the lung through its collapse. This paper does not allow a full discussion of these methods, many of which are of questionable merit, therefore, my remarks will be confined only to those having widespread acceptance and known to be of established value, with a superior background of experience, namely, artificial pneumothorax, intrapleural pneumolysis, phrenic neurectomy and thoracoplasty. Extrapleural pneumolysis, intercostal neurectomy, scalenotomy and direct cavity drainage are applicable in a few selected cases. This contribution is based upon 25 years' experience with artificial pneumothorax, during which time approximately 1700 cases have been subjected to it, in addition, about 1000 cases have had the benefits of such surgical collapse procedures as intrapleural pneumolysis, phrenic neurectomy and thoracoplasty. Extrapleural pneumolysis and direct cavity drainage were employed in a few cases.

When collapse therapy has been decided upon, the first method to be considered should be artificial pneumothorax, although some surgeons still contend that thoracoplasty is the method of choice. But I do not believe such statements come from those having pneumothorax experience, as, among the latter, the feeling is predominant that every candidate for collapse therapy should be granted a pneumothorax trial.

ARTIFICIAL PNEUMOTHORAX

Artificial pneumothorax is the simplest and most efficient method of putting the lung at rest by collapse. One great disadvantage, however, is the necessity of protracted continuation of the collapse, whereby the treatment often becomes a tiresome affair for the patient, yet, if all goes well, the patient ultimately has a good functioning lung instead of a permanently collapsed one,—as will be the case if major surgical procedures are adopted.

The danger of complications in pneumothorax is negligible, less than 2 per cent of our series died as a result of complications. Since using carbon dioxide for primary inflations, we have not had a gas embolism in 10 years.

Artificial pneumothorax should be used much earlier than is generally the custom. It is indicated in pulmonary tuberculosis with beginning infiltration and a positive sputum, as well as in moderately advanced cases. If no amelioration is forthcoming from a three to five months' routine of strict sanatorium care, and if clinical and roentgenologic study reveals a progression of disease, or at least the response to treatment has been unsatisfactory, a pneumothorax should be attempted at once. A good general rule is to induce a pneumothorax on every cavity case, unless there is some contraindication. When it is known which lung is the source of bleeding, hemoptysis is an obligatory indication for pneumothorax. Tuberculous pleurisy with effusion should be aspirated and continued as a controlled pneumothorax. This is also the best procedure to follow with tuberculous

spontaneous pneumothorax. Exudative types of tuberculosis are no contraindication—good results will be obtained, provided a satisfactory collapse is established, notwithstanding arguments that the consolidated lung cannot be collapsed. This is admitted, but if the patient survives the softening phase, the lung will at least be separated from the chest wall and active collapse can follow as excavation takes place. We have seen this successful time after time.

The contraindications include renal or cardiac failure and extensive emphysema. Tuberculosis of the larynx and intestines, unless uncontrolled and causing a significant hindrance in the patient's nutrition, is no contraindication, neither is controlled diabetes a contraindication.

My associates and I have often called attention to the constituents upon which successful pneumothorax therapy depends, but they may be repeated here. According to our experience, determining factors are (first) the type of disease, its character, degree of activity, complications and condition of the opposite lung, (second) the character of the pneumothorax, (third) social and environmental conditions influencing the length of treatment. If the latter issue is satisfactory, the results of treatment will depend (first) on the type of disease, (second) on the character of the pneumothorax, (third) on the condition of the opposite lung. Admittedly, cases with the disease confined to one side are preferable. But the presence of even active disease in the contralateral lung is not a contraindication per se. We have repeatedly witnessed the healing of a contralateral lung lesion following establishment of a satisfactory pneumothorax on the homolateral side. Cases with a more or less stationary cavity on one side, with progressive bronchogenic extension to the opposite lung, can best be treated by establishing a pneumothorax on the side of the fresh invasion. As collapse on the newly invaded side progresses, and if the mediastinum is mobile, it will shift and fibrosis will proceed on the cavity side. We have had numerous successes by following this technic. There should be no hesitancy in closing cavities as soon as possible by progressive collapse or compression, instead of relying upon partial or selective collapse in this type of case.

In fully 20 per cent of cases selected for pneumothorax, dense pleuritic adhesions will prevent any gas introduction, these require other surgical intervention (noted later), unless contraindications are present. Several years ago we analyzed a group of cases of the above type, wherein a pneumothorax was indicated but adhesions prevented any gas introduction. These cases were subjected to extended sanatorium care, with the result that less than 7 per cent recovered. Had the advantages of modern surgery been attainable, I am certain that fully 40 to 50 per cent would be alive and well.

In a second group of cases studied, pleuritic adhesions prevented sufficient functional rest and closure of cavities in approximately 40 per cent. While gas was introduced and a partial pneumothorax established, recovery followed in no more than 15 per cent. Thus, in 60 per cent of cases selected

for pneumothorax, it either cannot be used, or satisfactory collapse cannot be obtained. This latter class of case is perhaps subject to more debate as to the program to be followed than any other.

We have frequently seen unfortunate instances wherein an unsatisfactory collapse was continued for a lengthy period when it could be clearly shown that pleuritic adhesions inhibited closure of a cavity, undoubtedly, a small number of such cases will recover, but eventually in the majority, extension of disease into the opposite lung becomes manifest, or, if already present, such critical incursions will have been made that the patient's state is hopeless. It is painful to realize that the disease process is allowed to advance in so many cases when the advantages of surgery, if used earlier, would be so beneficial.

In a third group of cases subjected to pneumothorax the collapse was a satisfactory one—often in spite of adhesions—and approximately 50 per cent recovered. If one could persuade the patient to continue the pneumothorax for an appropriate length of time, and to give proper cooperation in taking the cure, the number of recoveries would be decidedly increased. That pneumothorax should be withheld until after a probation of sanatorium care is not in keeping with the advances made in the treatment of this disease by collapse therapy. Too many sanatoria do not utilize collapse therapy beyond artificial pneumothorax, and their first gesture toward surgery is confined to phrenic neurectomy. Beyond that, many institutions are unprepared to carry out the necessary collapse therapy program.

This brings me to a consideration of the surgical treatment of adhesions,—that is, the conversion of an unsatisfactory pneumothorax, because of adhesions, into a satisfactory one. We have never regarded the open operation appropriate for severing adhesions, but for years we did advocate active stretching of adhesions by gradually increasing the intrathoracic pressure—with end results that were far from satisfactory. In 1925, we adopted the closed intrapleural pneumolysis proposed by Jacobaeus, and I later modified it by substituting the high-frequency current for cutting purposes in place of the galvanocautery, which was defective because of the patient's reaction to operation, the character of cutting, and the too frequent incidence of complications.

As already stated, an uncollapsed cavity is a menace to the patient and others in close contact. If efforts to close tuberculous cavities by artificial pneumothorax have been defeated by adhesions, and the patient still raises a positive sputum after three to five months, one should consider surgical attack upon the retarding adhesions at once.

INTRAPLEURAL PNEUMOLYSIS

There is need of a better understanding on the part of those who ignore this most neglected of collapse therapy procedures. A tuberculosis specialist with no surgical training hesitates at attempting the operation—and rightly

so—for, while it is not difficult, some surgical training is necessary to prevent and combat complications which might arise. The surgeon undertakes it reluctantly because he lacks a pneumothorax experience, and often has no knowledge of thoracoscopy. Unaccustomed to operating under the guidance of the thoracoscope, and believing he can more accurately visualize the operative field, he prefers the open method of severing adhesions.

The open operation, however, is unnecessary, because one can place the thoracoscope in such a position as to afford examination of every part of the pneumothorax cavity, which is impossible with the unaided eye. After experience, one can recognize the structure of tissues much better with the thoracoscope and confidently sever large adhesions that could not be cut by the open operation without great risk to the patient.

The dangers of hemorrhage, bronchopleural fistula and empyema are slight when proper technic is employed. While we have given up the galvanocautery of Jacobaeus in favor of my electrosurgical method, we do not condemn the cautery as dangerous—we simply believe the electrosurgical method, while perhaps technically more difficult, is the method of choice because the undesirable aspects of the galvanocautery are excluded.

The operative technic has been fully discussed previously^{1,2,3,4}. For those uninformed about the operation, I will briefly state that in the closed intrapleural pneumolysis, instead of making the opening through the chest wall, after the resection of ribs, sufficiently large to permit surgical ligation and cutting of adhesions—which, after all, is a major operation for the patient—a site is selected for introducing the thoracoscope and after local anesthesia infiltration of that area, the optical instrument (thoracoscope) is introduced by means of a trocar and cannula. A study is then made of the pneumothorax cavity and a site selected for similarly introducing the cutting instrument under local anesthesia through a chest wall puncture. For additional enlightenment, I would refer to my publications.

Technically, as far as the patient is concerned, the operation is a very minor one, scarcely less objectionable than a pneumothorax refill or diagnostic puncture. Adhesions will be present in almost half of the cases selected for pneumothorax treatment, but they will not necessarily prevent a satisfactory collapse or compression of the lung, hence, the mere presence of adhesions is no indication for operation.

Intrapleural pneumolysis is indicated where roentgenologic and clinical evidence discloses (after three to five months' trial) that adhesions are retarding a satisfactory collapse of the lung, provided one can assume that recovery will take place after a satisfactory pneumothorax has been established. Furthermore, adhesions must be of an operable type, and the pneumothorax sufficiently large to permit manipulation of instruments. The operation is also indicated when uncomfortable symptoms from downward pressure on the stomach and liver are apparent (even in satisfactory pneumothorax) in endeavors to maintain a proper collapse by high intrathoracic pressure. A still further indication is one wherein adhesions have

become fibrous and are causing an early expansion of the lung by their contraction,—thus often inciting hemorrhage or recurrence of tubercle bacilli in the sputum

Complications In over 250 cases operated upon we have had no direct operative mortality. In our series only one death occurred for which the operation was indirectly responsible. We had three profuse hemorrhages early in our work but no instance of serious sequelae. Serous, hemorrhagic and purulent exudate occurred much too frequently while utilizing the galvanocautery of Jacobaeus. This and other disadvantages led me to perfect the instruments and adopt the high frequency method then widely applied in general surgery. Our first experience with the high frequency method, although superior to the galvanocautery, left much to be desired in the type of unit employed. When the Bovie Electrosurgical Unit* appeared on the market, with its new features for the control of bleeding, we tested it experimentally. Finding it fulfilled all requirements, we have since used it routinely, and attribute to the advantages of this unit our present low incidence of serous exudate (3.8 per cent), purulent exudate (2.5 per cent), and hemorrhagic exudate (1.2 per cent). Severe febrile reactions no longer occur.

The general conception of this operation is that only small adhesions, the size of one's finger, may be severed with safety. However, I have had repeated success in severing adhesions as large as the palm of the hand of an average man,—without hemorrhage or deleterious complications.

In a series of over 250 cases, 70 per cent have been clinically successful,—that is, the unsatisfactory collapse was converted into a satisfactory one and all patients were restored to working capacity with a negative sputum, whereas, before operation, over 90 per cent had a positive sputum and 85 per cent were bed cases.

Intrapleural pneumolysis is attracting the attention it justly deserves. Were it utilized to the extent it merits, fewer thoracoplasties would be performed on the class of cases wherein a pneumolysis is appropriate. We are convinced that three to five months' trial will determine the efficacy of a pneumothorax. If, after that period of time has elapsed, roentgenograms show evidence that adhesions are preventing closure of cavities, a thoracoscopic examination, which is as harmless as a pneumothorax refill, should be made to determine their operability. Adhesions found suitable for operation should be severed. If inoperable types are present, the useless pneumothorax should be discontinued and other surgical collapse procedures promptly put to use before the case is too far advanced.

PHRENIC NEURECTOMY

While intrapleural pneumolysis is the most neglected operative collapse procedure, one may reasonably state that phrenic neurectomy undoubtedly is the most abused. In 1912, Stuertz proposed resection of the phrenic

* Manufactured by The Liebel-Flarsheim Co., 303 West Third St., Cincinnati, Ohio

nerve to paralyze artificially the hemidiaphragm on the diseased hemithorax to provide functional rest of the lung. Resection of the nerve was followed by atrophy of the musculature of the diaphragm and its gradual rise into the thorax. Collapse of the lung, amounting to one-fourth to one-third its volume, took place.

The original operation was relatively short-lived, in approximately one-half to one-third of the cases, the diaphragm paralysis was of short duration or failed to occur at all. When the anomalies of the phrenic nerve became known, through the work of Felix and Goetze and confirmed by Plenk and myself, two operations were proposed—the exaeresis of Felix and the radical phrenicotomy of Goetze. Space does not permit a discussion of the merits of these two operations.

Based on the anatomical studies of Plenk and myself,⁵ the preferable approach to the phrenic nerve is through the subclavian triangle. One is thus in a position safely to evulse the nerve, as well as sever accessory nerve fibers, if encountered. It is unnecessary to remove the entire nerve, as we find that an 8 to 10 cm. length is sufficient to give a permanent paralysis.

Phrenic neurectomy is a minor operation, and while anomalies of the nerve exist in more than 25 per cent of cases, it is amazing that more complications do not occur. The operation should not be undertaken without a thorough knowledge of the topographical anatomy of the neck and familiarity with variations of the phrenic nerve. Ignorance of phrenic abnormalities is responsible for many accidents during operation, and fatal results have occurred even in the hands of competent surgeons. Damage to the vagus and sympathetic trunk is not uncommon,—also instances have been cited where no phrenic nerve was found. We, ourselves, have operated upon five patients who were referred to us after previous unsuccessful attempts by others to locate the phrenic nerve. In each case we found the phrenic nerve arising from the fifth cervical root far lateral to the scalenus anticus. A recent consultation had to do with a patient from whom a surgeon had removed a section of what was thought to be the phrenic nerve. The patient developed a Horner syndrome, but the diaphragm functioned normally. A second surgeon later reoperated upon the same case, and removed a section of a nerve—supposedly the phrenic—and the patient promptly exhibited a unilateral paralysis of the vocal cords. The diaphragm, however, still functioned normally. Certainly, such accidents should be avoided.

Indications The indications for phrenic neurectomy are

As an independent procedure in all cases wherein an artificial pneumothorax is indicated and attempts to introduce gas have proved futile or insufficient because of inoperable pleuritic adhesions which cannot be severed by the closed method of intrapleural pneumolysis, for social or economic reasons in cases when a prescribed course of pneumothorax is not possible.

Before every thoracoplasty because the improvement following an induced hemidiaphragmatic paralysis may be so marked as to avert the neces-

sity of a major surgical operation. A satisfactory hemidiaphragm paralysis (in favorable cases) occasions such improvement that the patient is rendered a far better surgical risk, also the sputum quantity and cough are markedly diminished, thus minimizing the danger of aspiration infection if a thoracoplasty is done. Its employment before thoracoplasty is also indicated since, by providing as much collapse as possible through the rising diaphragm, one may be able to reduce the number and length of ribs to be removed later. Through its use also the heart accommodates itself in stages to the increased functional activity that will be demanded of it as a result of thoracoplasty.

The value of phrenic neurectomy is indisputable as a supplement to artificial pneumothorax (for additional collapse) where non-operable adhesions are preventing a satisfactory lung collapse, and also as a test of the soundness of the contralateral lung. In cases with suspicious changes in the better lung, some surgeons are of the opinion that a phrenic neurectomy is of greatest value as a "test" operation before a thoracoplasty. Should the physical or roentgenologic findings increase after phrenic neurectomy, with exacerbation of fever, or other perturbing manifestations, an extrapleural thoracoplasty is absolutely contraindicated. Contradictory to this belief, close scrutiny of our material corroborates the affirmation that the result of a phrenic neurectomy as a "test" operation, cannot be accepted with complete confidence, since we have seen a contralateral lung lesion withstand the "test" operation, but exhibit activity after a thoracoplasty. We have also observed an essentially negative contralateral lung exhibit disease following the "test" operation, but pass through a complete thoracoplasty undamaged, although the diseased area in the contralateral lung was essentially the same before each procedure.

Other indications are threatened early oblitative pneumothorax where phrenic neurectomy is used combined with oleothorax to maintain collapse, and in the treatment of empyema occurring as a complication of pneumothorax where it serves to lessen the area of pyogenic membrane, also toward the end of a course of pneumothorax therapy in a case with an originally very extensively diseased lung, in order to diminish the capacity of the hemithorax so that it may accommodate a lung which has been shrunk by scar tissue changes—thus lessening the danger of reexpansion of excavated areas, secondary bronchiectasis, or retraction of heart and mediastinal contents.

Results The limits of this dissertation do not permit an analysis of our entire series of approximately 500 cases of phrenic neurectomy, performed according to the various indications and clinical types of cases. Exudative types of tuberculosis should be excluded, as this form seldom derives any benefit. The best results are obtained in the fibrocavicular and fibrocavicular cavernous cases (provided the cavities are not too large), who are candidates for a thoracoplasty. Our experience in this type of case has been extremely gratifying, as 15 per cent of cases selected for thoraco-

plasty, who had a phrenic neurectomy as a preliminary operation, have recovered, rendering the thoracoplasty needless. We have frequently remarked that cavities in the apex heal as a result of a phrenic neurectomy alone, provided a good diaphragm elevation is obtained. However, if the diaphragm pursues a horizontal course and is fixed by dense pleurodiaphragmatic adhesions, no benefit can be expected.

One should await maximum elevation of the diaphragm before proceeding with a thoracoplasty, the required time being from three to six months. If it is obvious that a phrenic neurectomy alone will not provide sufficient rest and collapse of the lung for healing to take place, one may proceed with the thoracoplasty, after waiting sufficiently long to observe its influence upon the integrity of the opposite lung.

EXTRAPLEURAL THORACOPLASTY

This operation should not be regarded as a last resort procedure. Such a mistaken conception is often responsible for delaying the operation until the patient becomes a bad surgical risk. There is urgent need of education regarding the role of thoracoplasty, for the impression that it is a shocking deforming operation, with high mortality and scant hope of cure, is a greatly mistaken one and should be rectified. In essentially stationary cavity cases with a good contralateral lung, if after a reasonable trial of the rest cure attempts to establish a pneumothorax have been prevented by adhesions, or if a pneumothorax has been established and adhesions of an inoperable type prevent closure of the cavity, and a phrenic neurectomy has not obtained the desired results, a paravertebral extrapleural thoracoplasty should be decided upon, provided there are no contraindications. The best results will be secured in chronic fibrous tuberculosis with evidence of shrinkage. If cavities are present, the thicker the wall, the less favorable will be the outcome.

The contraindications for thoracoplasty are the same as for an artificial pneumothorax, with the exception that disease of the contralateral lung, concerning which some leniency may be exercised in relation to a proposed pneumothorax, is an absolute contraindication to thoracoplasty unless it be arrested and not extensive. Poor surgical risks should be excluded, particularly if the operation is undertaken in a tuberculosis sanatorium, as the loss of a case is discouraging to others facing the same operation. The presence of incurable or uncontrollable organic disease is also a contraindication for thoracoplasty.

The selection of cases must be much more rigid than for pneumothorax. Exudative types of tuberculosis are unsuited for thoracoplasty, and patients whose resistance to tubercle bacilli invasion is inadequate, permitting progressive extension of disease, usually are poor risks. Limitation of operation to the age of 45 or 50 years is unnecessary if clinical and laboratory

studies indicate that the patient is a good surgical risk. Our oldest patient was 62, with tuberculosis of 15 years' duration. She made a perfect recovery.

A case with a combination pneumothorax, with a large cavity being held open by diffuse adhesions, would seem to offer an ideal indication for thoracoplasty. Yet, our experience suggests the contrary,—especially if there is a mediastinal bulge to the opposite side. Collapse of the chest wall increases the hernia, moreover, the presence of the pneumothorax often prevents a satisfactory collapse of the chest wall. The outcome in the above type of case can be greatly improved by artificially stiffening the mediastinum by precipitating a pleuritis of the bulge. The technic is simple and harmless. The patient is placed on the table with the pneumothorax side up, then, the second intercostal space is anesthetized as for a pneumothorax refill, and 2 c c of 1 per cent oil of gomenol and paraffin are slowly injected so that it will flow into the hernia. The patient remains in the same position for one-half hour, after which 50 to 100 c c of normal saline solution are slowly introduced through the same puncture, so that it will likewise flow into the bulge. The gomenol will now float upon the salt solution. Next, the patient is seated upright and the salt solution with gomenol is aspirated through another puncture at the base—this procedure prevents the formation of a diffuse pleuritis. With a normal pleura, a slight febrile reaction with exudate will occur, but it will be mild and will last only a few days. If there is no reaction, the procedure is repeated, using 2.5 per cent gomenol in the same manner. Again, if no reaction takes place, one repeats the process, gradually increasing the strength of gomenol until a reaction does occur. It may even be necessary to increase the strength up to 10 per cent. A successful issue is indicated by a gradual return of the mediastinum to the midline. This simple method of fixing the mediastinum also renders the patient a better surgical risk by eliminating the danger of mediastinal flutter. We avail ourselves routinely of this method in the last named type of case. This procedure should usually precede a thoracoplasty by two or three months, or even longer, and should also come before the preliminary phrenic neurectomy has been performed.

If the pneumothorax is a small one, it is better to permit the lung to expand before attempting the thoracoplasty.

I have no intention of going into the technic of thoracoplasty, but some of the essentials ought to be pointed out. Routinely, in the presence of underlying disease in the upper half of the hemithorax, we perform the upper phase first, contrariwise, if the pathologic lesions are chiefly in the lower lobe, we do the lower phase first. The operation should be done in two or more sittings. For poor risk patients, we prefer the graded thoracoplasty suggested by Hedblom.

The length of segments and number of ribs to be resected must be individualized in each case—depending upon the underlying lesion and the condition of the patient. Adequate sections of ribs should be severed close

to the transverse processes. In a number of cases operated upon by others as well as in some of our early cases, the sections of ribs removed were too short, the cavities remained open and the removal of regenerated rib became necessary. This latter procedure is an altogether unpleasant one, as the removal of portions of regenerated rib sufficient to provide adequate collapse is sometimes a tedious operation. Because of the above error, one of our early cases was operated upon nine times before the cavity was successfully closed.

When large upper lobe cavities are present in a case with a pneumothorax, we routinely follow the upper phase operation by an accessory lateral one, including the first rib, then proceed with the lower phase, unless only a partial thoracoplasty is intended. We feel that a much better collapse of large cavities is effected by the above sequence of operation. Partial thoracoplasties on upper lobe cavity cases have often produced disappointing results, necessitating reoperation to secure a better collapse.

According to our experience, if the case presents a large cavity extending to the second rib in front, and if the lung over the cavity is diffusely adherent to the chest wall while the rest of the lung is completely collapsed by a pneumothorax, the upper phase operation should be done first, resecting, if possible, substantial segments of the upper five ribs and all of the first. During the operation, a 14 gauge needle should be left in position through the chest wall so that, as the chest wall falls in, air may pass out of the pleural cavity. The needle must be kept away from the operative field and withdrawn after the operation is completed. Within a week or 10 days the remaining portions of the above ribs are resected close to the sternum through a midaxillary incision. Between operations a film will indicate the advisability of aspirating air before the second operation, but a needle is again placed in position during the second operation to allow air to escape. Within a week or 10 days, the lower phase operation follows with the needle again in position. Following the completed thoracoplasty, air is aspirated at regular intervals and the chest wall tightly strapped to obliterate the pneumothorax. The patient is placed in the author's thoracic hammock as soon as possible to effect a better chest wall collapse during the period of osteogenesis and to prevent deformity.

In performing a thoracoplasty in combination with a pneumothorax, or in cases with free pleural space, one should exercise great caution in stripping the rib of its periosteum so as not to tear through the pleura and possibly invert a bleeding intercostal vessel into the pleural cavity. In case of such an accident one should make sure that no bleeding vessel is inverted before closing the torn place. I once witnessed this accident in the hands of a very experienced and clever thoracic surgeon. Although all visible bleeding in the wound was arrested at the time of operation, the patient died several hours later. Autopsy disclosed the cause of death: hemorrhage into the pleural cavity.

After a thoracoplasty has been decided upon, the patient is prepared for operation. If he has spent months at bed rest and has normal temperature, it is advisable to have him sit up in a reclining chair, increasing the hours day by day until six hours have finally been reached. Then short walks are given—provided, of course, that febrile reactions do not take place. This plan improves the cardio-respiratory tone. Complete laboratory studies should be repeated, and blood transfusion given if indicated. Blood chemical studies, kidney function tests and an electrocardiogram should be made. The patient should be trained in cavity drainage, the time noted when this is completed,—and the hour of operation then scheduled for a time when the cavity is essentially empty. One week prior to operation the patient is placed upon a protein-free, carbohydrate-rich diet with abundant water, and hard candy is sometimes given after meals. He is also prepared psychically for operation, and 24 hours before the procedure, he is placed in an oxygen tent for one-half hour out of every three for purposes of hyperventilation. We are sure that this plan has contributed much to our low operative mortality.

Preoperative medication in nervous and apprehensive patients consists in luminal, oral sodium, or nembutal the night before operation to insure a good sleep. This medication may be repeated three hours before operation if necessary. One-half hour before operation we usually give $\frac{1}{3}$ grain of pantopon, if there is no idiosyncrasy. In good surgical risk cases, with normal blood pressure, we often administer pernoston or sodium amytal intravenously in hypnotic doses. The operation is performed under local anesthesia with 1 per cent novocain-suprarenin, and light ethylene anesthesia. During operation a constant check is made upon the blood pressure, pulse and respiratory rate, and the moment any suggestion of shock appears, the operation is concluded. Until a few years ago, we made an effort to perform the operation quickly, since then, we take more time—25 to 30 minutes if all goes well. After operation the patient is again placed in the oxygen tent for 24 hours as before operation. Intravenous transfusion of blood, saline solution or acacia is given if necessary.

Nurses with special training should be in charge of these cases to support the chest wall during coughing and at the same time encourage the patient to raise the required amount of sputum. If necessary, opiates are used to control pain during the first two days following operation.

Before the next operation the case is carefully studied and prepared. As soon as possible after the completed posterior operation, the patient is placed upon the operated side in the thoracic hammock³. The hammock is elevated from the bed, this increases the chest wall collapse and prevents deformity. Daily resting (for several hours) in the hammock is continued for three months, during which time the chest is kept tightly strapped.

We have experienced no death from postoperative shock, wound infection or hemorrhage in our series of 150 cases. Three postoperative deaths within a week were due to cardiac failure. The remaining fatalities were

due to aspiration pneumonia, progressive tuberculosis in spite of the operation, or to tuberculosis of the intestines and from other causes not related to operation

The results of a well performed thoracoplasty compare favorably with the results obtained from artificial pneumothorax. In our series of 150 cases upon whom 360 operations have been performed, the clinically well group totals 70 (46.6 per cent). The improved group comprises 36 cases (24 per cent). They are capable of working but tubercle bacilli are occasionally found in the sputum. No doubt half will recover. In nine (6 per cent) who still have a positive sputum it is probable that additional collapse will be necessary. Three (2 per cent) have died as a direct result of the operation from cardiac failure, 14 (9.3 per cent) died of causes indirectly due to operation, such as aspiration pneumonia, 18 (12 per cent) died of causes not related to the operation, such as intercurrent disease, accidents, etc.

The results of surgical treatment of pulmonary tuberculosis are stimulating, and it is extremely gratifying to know that every tuberculosis sanatorium or hospital where tuberculosis is accepted has a number of patients who can be restored to health and self-support by the application of modern thoracic surgery, instead of being left to await a certain dissolution of soul and body.

There has been a gradual awakening on the part of those accepting the responsibility for the treatment of pulmonary tuberculosis to the fact that collapse therapy, particularly surgery, offers a hope unattainable by the routine sanatorium regimen. The application of collapse therapy to the fullest extent that it is indicated would be facilitated by better cooperation between the medical tuberculosis specialist and the thoracic surgeon, in institutions where a strictly medical and surgical service exists, and requires transfer of cases for operation from one service to the other. The ideal situation exists when the phthisiotherapist is qualified by training and experience to assume entire responsibility from both the medical and surgical standpoint so as not to necessitate, as it were, the changing of pilots in midstream. Successful collapse therapy, similar to urology, laryngology, and gynecology, is largely a one-man job. I predict that the tuberculosis specialist of the future will have both adequate medical and surgical training to conduct the treatment of pulmonary tuberculosis according to the indications and will not, as is now often the case, call in the thoracic surgeon when the case has become too far advanced for surgical relief.

The material referred to in this contribution is from the combined service of myself and associates, Dr Ray W. Matson and Dr Marr Bisailon.

OBSERVATIONS ON THE DIAGNOSIS AND TREATMENT OF PERIPHERAL VASCULAR DISEASE*

By EUGENE M LANDIS, *Philadelphia, Pennsylvania*

For the diagnosis, prognosis, and effective therapy of peripheral vascular disease it is essential to divide patients into two groups (a) those whose symptoms are due to simple spasm with no, or at most slight, organic vascular obstruction, and (b) those whose symptoms are due primarily to advanced organic disease of the arteries. Recent advances in the surgery of the sympathetic nervous system have made it highly desirable to detect early in the course of peripheral vascular disease, whether the flow of blood to an extremity is diminished by simple arterial spasm, or by obliterative structural disease of the arteries. In treatment the best results can be obtained only if beginning organic occlusion is discovered before it has reduced too greatly the normal capacity of the blood vessels to dilate.

The several tests available for detecting early organic vascular obstruction, though different in method, are similar in principle. The surface temperature of the cold, exposed extremity is measured thermoelectrically. Vasoconstrictor tone is then abolished in the part under observation and the rise in surface temperature is recorded. The level to which skin temperature rises during complete vasodilatation has been determined in persons with normal peripheral circulation. If the surface temperature fails to reach this normal level in a room at suitable temperature, it can be concluded that the arteries supplying the part are unable to dilate owing to organic changes in their walls.

Vasodilatation of the peripheral vessels may be induced by many procedures, but we have chosen to use the simple expedient of immersing two extremities in warm water^{1,2} verifying abnormal findings in most instances by anesthetizing the posterior tibial nerve³. In completely normal subjects immersing the forearms for 35 minutes in water at 43 to 45° C dilates the cutaneous vessels of the lower extremities and elevates the surface temperature of the toes to 31.5° C or more. Conversely, immersing both feet and legs in warm water for 35 minutes normally elevates the surface temperature of the fingers to 31.5° C or more.

Patients with coldness, blueness or pain in the lower extremities who show under suitable conditions a normal elevation of skin temperature (ie to 31.5° C or more) are certainly free from significant organic arterial obstruction (figure 1). When skin temperature fails to reach 31.5° C but still reaches 26° C or more (figure 2) only a moderate grade of organic occlusion is present. In such patients considerable benefit can be expected from contrast baths, local heat, diathermy, vasodilator drugs, the warm

* Read at the Chicago meeting of the American College of Physicians, April 16, 1934.
The expenses of this study were defrayed in part by a grant from the Philadelphia Heart Association.

cradle or sympathetic ganglionectomy, all of which increase blood flow, temporarily or permanently, by dilating those vessels which are still capable of expansion

FIG 1 Normal vasodilator response observed in a patient with bilateral thrombophlebitis. In this and subsequent charts L1 and R1 indicate the skin temperature of the left and right great toes, respectively, R T, the room temperature. The shaded area below indicates the period during which the forearms were immersed in warm water. (From Landis and Gibbon,² by permission of the *Archives of Internal Medicine*)

FIG 2 Vasodilator response in a patient with arteriosclerosis. The response was only partial in the left foot and was much delayed in the right foot. (From Landis and Gibbon,² by permission of the *Archives of Internal Medicine*)

In the advanced stages of peripheral vascular disease the arteries become more or less rigid owing to structural changes in their walls. These diseased vessels have not only abnormally small lumina but they may be unable

to dilate even when vasoconstrictor tone is abolished. Skin temperature then fails to rise (figure 3) during the period when vasoconstrictor tone is

FIG. 3. Chart showing complete absence of vasodilator response in a patient with advanced diabetes and arteriosclerosis with gangrene. (From Landis and Gibbon,² by permission of the *Archives of Internal Medicine*.)

abolished. After the arteries have thus lost their power of dilating, the therapeutic procedures mentioned previously cannot be expected to increase blood flow and, in fact, they usually fail to improve the nutrition of the tissues in the extremity. Eventually many of these patients with conspicuous organic occlusion suffer from trophic changes, ulceration and gangrene, leading finally to amputation. Such patients present a particularly harassing therapeutic problem since the usual methods of increasing peripheral circulation all depend fundamentally upon the residual power of vasodilatation. At the University of Pennsylvania we have been interested during the past three years in the problem of attempting to increase peripheral blood flow in this unfavorable group of patients. It can be expected that any procedure which increases blood flow in spite of advanced organic occlusion will reduce pain, aid healing, and delay or possibly prevent the appearance of gangrene. Rest pain and ulceration frequently require the amputation of extremities which, if they could be preserved, would prevent the patient from becoming an economic liability.

Poiseuille, early in the last century, described the laws which control the flow of fluid through a rigid tube. He observed that the amount of blood flowing through a capillary tube depends upon the fall in pressure along the tube. This relationship can be demonstrated clearly in the living animal by measuring simultaneously capillary blood pressure and the rate of blood flow in single capillaries of the frog's mesentery.⁴ Inserting a minute glass pipette into a single capillary makes it possible to follow the variations in capillary blood pressure which result from spontaneous arteriolar dilatation and constriction. Though capillary blood pressure varies considerably, venous pressure remains approximately constant. The drop in pressure from the capillary to the vein, represented in figure 4 by the shaded vertical columns, can be at one moment very small, at another quite

large The rate at which blood flows through the observed capillary follows faithfully each variation in capillary blood pressure In other words, when capillary and venous pressures are equal the drop in pressure along the capillary is minimal and blood flow ceases On the contrary, when the drop

FIG 4 Showing relation between capillary blood pressure and the rate of blood flow in a single capillary of the frog's mesentery (From Landis,⁴ by permission of the *American Journal of Physiology*) The vertical shaded areas represent the drop in blood pressure from capillary to vein

in peripheral blood pressure is large, flow may become too rapid to measure microscopically Thus, it may be expected that, if the peripheral drop in blood pressure be increased artificially, blood flow may be made greater

In the presence of a rigid system of arteries, incapable of dilatation, the total fall in pressure in the peripheral vascular system may be increased in two ways, (a) by elevating systemic blood pressure, or (b) by diminishing venous pressure The first method is generally impracticable for numerous and obvious reasons It seemed possible, however, that applying negative pressure periodically to the skin of the extremity might increase blood flow by temporarily reducing venous pressure below atmospheric pressure

An aluminum box was built large enough to accommodate the lower extremity to a point six inches above the knee where the thigh was surrounded by an air-tight rubber cuff (figure 5) An air pump, valve, mercury manometer, and relay were so arranged that the lower extremity was exposed alternately and automatically to a negative pressure of 80 to 120 mm Hg for 25 seconds and a positive pressure of 60 to 80 mm Hg for five

FIG 5 Diagram of aluminum box and double cuff (PR, DR) used for applying suction and pressure to the surface of the lower extremity (From Landis and Gibbon,⁶ by permission of the *Journal of Clinical Investigation*)

seconds Figure 6 indicates diagrammatically the rapidity with which pressure is changed, only 3 seconds being required for the shift from +80 mm Hg to -120 mm Hg. The normal difference between mean arterial and venous blood pressures is about 80 mm Hg. During suction this peripheral drop in blood pressure (vertical shaded areas in figure 6) is

FIG 6 Showing diagrammatically (a) the duration of the alternate periods of suction and pressure, and (b) the rapidity with which the changes in pressure are accomplished

considerably increased. The skin becomes red as the capillaries and veins are filled with blood. To empty the capillaries and veins rapidly at the end of 25 seconds of negative pressure, air is pumped rapidly into the box and pressure is elevated within three seconds to +80 mm Hg. The skin

blanches and the vessels are emptied through the veins to afford a reservoir into which fresh arterial blood may be drawn by the next period of negative pressure. The net result of this alternating suction and pressure is to increase considerably the average drop in blood pressure from artery to vein. Theoretically this should increase proportionately the flow of blood through the peripheral vessels of the extremity.

Prolonged ischemia produces local coldness, cyanosis, intermittent claudication, rest pain, and eventually ulceration or necrosis of tissue. If it is true that suction and pressure increase the local supply of arterial blood, these manifestations of ischemia should be relieved, at least to some degree. Landis and Gibbon^{5,6} showed in normal subjects under carefully controlled temperature conditions that blood flow, as indicated by skin temperature, was greater in the limb exposed to pressure variations. It was concluded that to obtain maximal effects on blood flow it is advisable to have (1) relatively brief periods of suction, (2) intermittent brief periods of pressure, and (3) diminished vasoconstrictor tone, the last being necessary in order that the reservoir for accommodating blood drawn in by each suction period might be adequate.

This paper comprises a brief summary of the effects of suction and pressure on the various manifestations of reduced blood flow in a series of 16 patients with advanced peripheral vascular disease. The disease was, in each instance, of long standing, the patients suffered from thromboangitis obliterans, simple arteriosclerosis, or diabetes with arteriosclerosis. Twelve of these patients had no vasodilator response in the observed extremity, while the remaining four showed in the most severely involved extremity a rise of skin temperature to between 24 and 27° C.

With the patient semi-recumbent, the most severely involved extremity was exposed to pressure variations for periods of one to two hours, from twice daily to once weekly, for totals of 2 to 112 treatment hours. Suction was between -80 and -120 mm Hg, pressure between +60 and +80 mm Hg. Suction and pressure were applied alternately for 25 and 5 seconds, respectively, except in one instance in which intervals of 50 and 10 seconds were used for part of the time (Table 3, Patient C3). When skin temperatures were measured conditions were carefully controlled as described previously.⁶ Vasoconstrictor tone was reduced by enclosing one forearm in an electric heating pad kept warm enough to produce slight generalized sweating.

Table 1 presents a summary of a series of short observations on the effects of suction and pressure on skin temperature. In every instance the foot which was exposed to pressure variations became warmer than the control extremity. The final temperature reached was always above that attained by the extremity when maximal vasodilatation was produced by abolishing vasoconstrictor tone. The digits of the foot exposed to suction and pressure became, on the average, almost 6.0° C warmer than the untreated, or control, digits. The smallest difference in temperature was

| | | | | Untreated extremities | | 1.8 |

22° C (Patient 3), the largest 98° C (Patient 2). The difference between the skin temperatures of the treated and untreated extremities was usually large enough to be perceptible to the hand of the examiner, and to the patient himself.

Skin color was estimated according to the Lewis⁷ scale in which XV and XVI correspond to complete cyanosis, V to bright hyperemia, and VII or VIII to normal skin color. In areas of frank gangrene (table 2) no change in color could be detected, probably since the affected vessels were already thrombosed and circulation was at complete standstill. The digits of patients with severe pain, with or without ulceration, were more or less cyanotic. In some it required but a few alternations of pressure to change this cyanosis to normal skin color. The skin then became deeply red during suction and pale during pressure as does normal skin. Small areas remained cyanotic for several days, but the normal coloration eventually

extended over the whole skin surface. The hyperemia produced during the first few alternations in pressure is maintained for some hours, and usually becomes more and more lasting as treatment continues. In some, however, cyanosis persisted in the intervals between treatments. In three instances striking improvement in skin color has been followed during the winter and has remained in spite of severe cold.

Most of these patients suffered also from severe and often intractable rest pain, which was either constant or occurred in brief episodes, usually worse at night. Two types of observations may be summarized. First, to observe acute effects extremities were exposed to pressure variations during episodes of pain. Protocols 1 and 2 indicate the relief of pain.

ACUTE EFFECTS OF SUCTION AND PRESSURE ON REST PAIN

Protocol 1 Patient had thromboangitis obliterans with large gangrenous slough in palm following amputation of finger in another hospital. Patient was unable to keep hand above the level of the sternum owing to excruciating rest pain.

12 15 p.m. Pain present. Hand placed above level of sternum in modified box. Suction (80 mm Hg) and pressure (60 mm Hg) applied for 25 and 5 seconds, respectively.

12 30 p.m. No pain.

1 45 p.m. No pain,—pump stopped for 2 minutes. Severe pain in palm.

1 47 p.m. Pump started again.

1 48 p.m. Pain less.

1 49 p.m. Pain gone,—itching remains.

2 30 p.m. Hand removed from box. Pain recurred after patient returned to ward.

Protocol 2 Patient had arteriosclerosis and ulceration of two toes with rest pain preventing sleep in spite of sedatives.

| | |
|----------------|--|
| 11 00 p m | Severe pain wakened patient |
| 11 45 p m | Pain still present Patient placed in apparatus with suction (120 mm Hg) and pressure (80 mm Hg) for 25 and 5 seconds, respectively |
| 12 midnight | Pain gone, patient drowsy |
| 12 50-4 15 a m | Patient sleeping |
| 4 15 a m | Leg removed from apparatus Patient slept remainder of night |

obtainable The first patient was unable to keep the hand higher than the sternum owing to severe rest pain At 12 15 p m, when pain was present, the hand and forearm were placed in the apparatus so that they lay in a position known to produce pain Fifteen minutes after pressure variations had begun the pain disappeared although holding the hand in the same position was unbearable under ordinary conditions The pain remained absent until 1 45 p m when the pump was stopped for two minutes This was followed by severe pain in the palm Starting the pump again caused the pain to disappear leaving only some residual itching Pain was absent for the remaining hour of the observation The pain returned, however, several hours after suction and pressure were discontinued, and amputation was done primarily on account of the size of the slough Another patient (protocol 2) had ulceration with severe rest pain due to arteriosclerosis This pain had prevented sleep, in spite of moderate sedation, in the hospital At 11 00 p m severe pain wakened the patient, the affected extremity was placed in the apparatus at 11 45 p m, while pain was still present Fifteen minutes later the pain had disappeared and the patient was drowsy Thereafter he slept until 4 15 a m, when he was removed from the apparatus and continued sleeping during the remainder of the night

In the many hours during which extremities have been exposed to these pressure variations true rest pain has not been observed during treatment Discomfort sometimes appeared owing to drying of ulcers This can be avoided by covering the raw surfaces with vaseline As a rule patients, previously exhausted by continued pain, fall asleep almost immediately after the extremity is placed in the apparatus The continuous application of negative and positive pressure over long periods of time was attempted It was found quite early, however, that the rubber cuff at the proximal end of the apparatus became uncomfortable usually after two to four hours, making it impossible to prolong pressure variations uninterruptedly beyond this period

While temporary relief of pain was obtained even when areas of frank gangrene were present, pain returned more or less quickly after the limb was removed from the apparatus, as indicated in protocol 1 and table 3 Eventually amputation was performed in all four patients with frank gangrene (table 4) Three of this group were treated only a few hours, the totals ranging from 2 to 11 hours The fourth patient was treated for a

| 3 | Originally walked $\frac{1}{3}$ block | Increased to 1 block | |
| 4 | Originally walked $\frac{1}{2}$ block | Increased to 2 blocks | |
| 5 | Originally walked $\frac{1}{4}$ block | No effect (only 3 hours' treatment) | |
| 6 | Originally walked $1\frac{1}{3}$ blocks | Increased to 10-12 blocks | |

TABLE IV

Effects of Suction and Pressure on the Healing of Indolent or Enlarging Ulcers Associated with Peripheral Vascular Disease

I Patients with local gangrene

| Diagnosis | Size of ulcer | Course | Effect |
|-----------------------------|--------------------------------------|--------|-----------|
| 1 Thromboangitis obliterans | Gangrenous slough 5 × 6 cm | Acute | None |
| 2 Thromboangitis obliterans | Gangrenous area 1 × 2 cm | Acute | None |
| 3 Arteriosclerosis | 2.5 × 2.2 cm Large central slough | Acute | Temporary |

II Patients with ulcers but without frank gangrene

| | | | |
|------------------------------|--------------|----------------------|---------|
| 1 Thromboangitis obliterans | 1.0 × 1.5 cm | (Indolent-1 month) | Healed |
| 2 Arteriosclerosis | 1.0 × 0.9 cm | (Acute) | Healed |
| | 0.7 × 0.8 cm | | Healed |
| 3 Arteriosclerosis, diabetes | 2.0 × 1.1 cm | (Indolent-3 months) | Healing |
| 4 Arteriosclerosis | 1.2 × 1.4 cm | (Indolent-4 months) | Healed |
| | 1.0 × 3.0 cm | | Healed |
| 5 Thromboangitis obliterans | 1.0 × 1.2 cm | (Enlarging) | Healed |
| 6 Thromboangitis obliterans | 0.8 × 1.0 cm | (Indolent-3½ months) | Healed |
| 7 Thromboangitis obliterans | 0.8 × 0.9 cm | (Indolent-5 months) | Healed |

total of approximately 50 hours with conspicuous, but only temporary, relief, amputation was eventually necessary

Patients with indolent or slowly enlarging ulcers, but without frank gangrene, large sloughs or extending necrosis, often obtained striking relief from rest pain. Sleep ordinarily became possible without sedatives after a few days. The results in patients with intermittent claudication were difficult to estimate and have been less striking, though in general slow improvement was observed. The subjective nature of the symptoms and the possibility of spontaneous recovery make it advisable to reserve judgment.

The diminished blood flow of peripheral vascular disease leads eventually to local gangrene, or to indolent ulceration which is resistant to treatment. Patients with frank gangrene did not improve significantly during or after exposure to pressure variations (table 4). One patient with a large sloughing ulcer under the malleolus showed temporary improvement, but very slow extension of the slough and continued pain made amputation eventually necessary. Those patients who had indolent ulcers without frank gangrene were markedly improved. The ulcers had, in some instances, been indolent or enlarging under treatment with antiseptics and heat for periods of several

FIG 7 Showing slight improvement of vasodilator response (right lower extremity) in a patient with thromboangiitis obliterans after prolonged use of suction and pressure

months before pressure variations were used. The healing, which occurred during application of suction and pressure, was accompanied by improvement of skin color and diminution of rest pain.

The rise in skin temperature, the improvement of skin color, the diminution of rest pain and the healing of previously indolent ulcers indicate that alternate suction and pressure increases blood flow at least temporarily. At the present time it is impossible to do more than speculate upon the permanence of this improvement. Complete and lasting recovery depends upon the development of adequate collateral circulation. Sufficient time has not elapsed to determine to what extent increased blood flow depends upon the continued use of pressure variations.

In some patients collateral circulation develops slowly during and after treatment. Figure 7 illustrates observations on a patient in whom no response was observed during March 1933 in the right lower extremity. After the use of suction and pressure the right extremity showed during January 1934 a slight, but definite, increase in temperature during the immersion of forearms in warm water. The untreated extremity, on the contrary, exhibited on the second examination less vasodilator response than before. The patient illustrated in figure 8 showed no change in vasodilator response between February 1932 and March 1934 although considerable treatment was given during late 1933 and early 1934. Clinical improvement was distinct, however, rest pain and cyanosis disappeared almost completely, and an indolent ulceration following amputation healed without incident during the use of negative and positive pressure. The patient is at present ambulatory and able to work.

From the results summarized above it may be concluded that alternate suction and pressure increase blood flow temporarily, even after organic vascular disease has diminished, or abolished, vasodilatation. The changes of skin color, the alleviation of rest pain, the accelerated healing of indolent ulcers amplify the earlier evidence based on studies of skin temperature^{5,6}. Concerning the real therapeutic value of this procedure little can be said until a large series of carefully controlled and extensive clinical observations have been made. Reid and Herrmann have described the development of collateral circulation in patients with peripheral vascular disease after prolonged treatment by means of pressure variations in cycles of five minutes. They utilized at first⁸ Bier's method in which negative pressure was applied very gradually for two minutes, maintained at -70 mm Hg for one minute and then gradually relieved during two minutes, no positive pressure being used. More recently they⁹ have adopted a procedure involving briefer periods of negative pressure alternating with positive pressure in cycles as short as 15 seconds.

Contraindications to the use of suction and pressure can be given at this time on theoretical grounds only. Active or acute infection may well be unfavorably influenced by the procedure. Osteomyelitis, however slight, makes it unlikely that complete healing of cutaneous lesions can be obtained.

FIG 8 Showing no change in vasodilator response of patient with thromboangitis obliterans (subacute type) after the use of suction and pressure. Pain and cyanosis were much improved but blood flow was not sufficiently affected to change skin temperature when vasoconstrictor tone was diminished.

as long as drainage from beneath continues. When large masses of tissue are actually gangrenous, or sloughing, only temporary relief has so far been observed.

SUMMARY

It is necessary to detect beginning organic obstruction as early in the course of peripheral vascular disease as possible, since the therapeutic measures available depend to a large degree upon the ability of the blood vessels to dilate. Unfortunately, many patients reach the hospital after peripheral vascular disease has advanced to the stage when the arteries are no longer able to increase their diameter, though vasoconstrictor tone is entirely abolished. Even under these unfavorable conditions, however, it is still possible to increase blood flow by means of alternate suction and pressure. This procedure elevates skin temperature conspicuously, tends to relieve cyanosis, diminishes rest pain and favors, at least temporarily,

the healing of superficial, indolent ulceration. Whether or not the development of collateral circulation can be so stimulated as to return tissue nutrition permanently to a normal state is not yet certain. The practical importance of suction and pressure in the treatment of peripheral vascular disease will necessarily depend to a great extent on the degree to which collateral vessels take over the function of those arteries which are closed by disease. There are indications that even if the patient can only be aided temporarily over crises of rest pain or ulceration, time will be gained for the natural development of collateral circulation so that a certain number of mutilating operations can be avoided.

THE ETIOLOGY OF ARTERIAL HYPERTENSION¹

By SOMA WEISS, M D , F A C P , *Boston, Massachusetts*

THE two questions most frequently asked of investigators engaged in the study of arterial hypertension are (1) how do you treat patients with arterial hypertension, and (2) what is the cause of arterial hypertension? The answers to these closely related questions are always given with embarrassment and humility. The answer to the first question is relatively simple, for there are but few therapeutic measures the beneficial nature of which is proved to be specific. The answer to the second question, which I intend to consider here, is difficult and at best incomplete.

Extensive and reliable experimental data are available indicating that arterial hypertension may be induced in animals in several ways. In addition, observations on patients with arterial hypertension have disclosed numerous alterations in the physiological and chemical functions. It is because of the many possible ways of inducing experimental hypertension, and because of the numerous deviations in bodily functions associated with hypertension, that the study of the etiology of *clinical* hypertension is so difficult. What we desire to know is the cause of arterial hypertension as it exists *in man*. The fallacies most frequently encountered in the solution of this problem are (1) generalizations from experimental observations in animals, without proper appreciation of the clinical problems, (2) an inadequate clinical study of the patient as to the type of arterial hypertension and as to its secondary complications, (3) the frequent misinterpretation of a finding which coincides with or is the result, rather than the cause, of arterial hypertension, (4) the inaccuracy of the methods applied.

Data bearing on the etiology of arterial hypertension have accumulated so rapidly during recent years that unless one has had experience in investigating the varied aspects of the problem one is completely lost in the maze of data. With a full realization that the problem is far from being settled, I shall present a viewpoint based on a critical analysis of the literature and on some personal experience.

The main lines of approach to the problem may be divided into the following groups: (1) the role of circulating substances, including hormones, (2) the influence of the nervous system, (3) the reactivity of the vascular system and mechanical factors, (4) infections and allergy, and (5) constitutional factors.

¹ Read at the Chicago meeting of the American College of Physicians, April 18, 1934. From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

1 THE RÔLE OF CIRCULATING CHEMICAL SUBSTANCES IN ARTERIAL HYPERTENSION

This approach to the etiology of hypertension is perhaps the most obvious, particularly since examples of hormones with a vasoconstrictor effect are available. The search for chemical substances in the blood and in the urine actually goes back to the first clinical concepts of nephritis established by Bright and Johnson. It would be useless to enumerate here investigations of all the substances held responsible for the development of arterial hypertension. It is clear from the literature that glucose, salt, purine and protein substances are not etiological agents. Among the chemical theories which have interested investigators in recent years, there are several of particular interest.

Guanidine The first is that of Major^{2,3,4} who proposed that retention of guanidine bases is responsible for essential hypertension. In support of his assertion he has demonstrated that administration of certain guanidine compounds produces a rise in the blood pressure of experimental animals, and has claimed that in patients with essential hypertension the excretion of guanidine bases in the urine is diminished, and the guanidine content of the blood increased. Major's contention cannot be considered valid at present (1) because the amounts of guanidine compounds administered to animals are relatively large, and (2) particularly because the reliability of the chemical methods which he used for the demonstration of guanidine bases in the blood and urine is questionable^{5,6}. Kleeberg,⁷ using a colorimetric method similar to that used by Major, has observed an elevation of the guanidine content of the blood in patients without hypertension. In patients with hypertension, he found that the guanidine content was elevated only when there was an accumulation of protein derivatives and products of intestinal putrefaction; in a number of cases he observed normal colorimetric values. Turriès and Robert⁸ and likewise Jackson⁹ in our clinic were unable to establish a correlation between hypertension and the guanidine content of the blood. It should be remembered that more recent experiences with creatinine and urea clearance tests indicated that an impaired excretion of some compounds may occur in patients with hypertension without necessarily bearing on the etiology of the condition.

Cholesterol Schmidtman¹⁰ has observed a temporary elevation of the blood pressure in rabbits following prolonged cholesterol feeding. Westphal,¹¹ on feeding rabbits a high cholesterol diet, observed that their blood pressure rose concomitantly with an increase in the serum cholesterol. Investigating a series of 80 cases of essential hypertension, he also found that the cholesterol level was above the normal range in 71 per cent of the cases. Weil and Guillaumin¹² and Askanazy¹³ found high cholesterol values in the plasma of patients with hypertension. Thus, on the basis of observations on man as well as of experiments on animals, Westphal and others consider cholesterol as one factor in the genesis of essential hyper-

tension Although the experimental work of Schonheimer,¹⁴ Shapiro¹⁵ and Tholldte,¹⁶ and the chemical studies in man of Mjassnikow,¹⁷ Loewenstein,¹⁸ Harris and Lipkin¹⁹ have shed much doubt on the rôle of cholesterol in the production of arterial hypertension, we²⁰ reinvestigated this problem in 75 cases of hypertension Our study revealed that patients with secondary renal complications were more apt to show hypercholesteremia than were those with secondary cardiac involvement On the other hand, of 37 patients with uncomplicated hypertension, only five showed an unexplained hypercholesteremia We have therefore concluded that the elevation of cholesterol is the result, rather than the cause, of changes in the cardiovascular system in arterial hypertension

Potassium-Calcium Ratio Since experimental observations^{21, 22, 23, 24} suggest that changes in sympathetic-parasympathetic and potassium-calcium balance can be detected by their effect on the action of hormones, Kylin²⁵ investigated the relation between the reaction to epinephrine and the potassium-calcium ratio He observed that in cases with a potassium-calcium ratio of from 0.7 to 2.15, which is within his normal range, there were normal reactions to epinephrine The blood pressure curve of patients with essential hypertension having a ratio over 2.15 was consistently vagotonic, that is, the patients exhibited a fall in blood pressure after epinephrine Kylin, Brenms²⁶ and Loewenstein¹⁸ found a definite rise in potassium content in cases of essential hypertension, while calcium values were either at, or below, the lower limits of normal Jansen²⁷ found that in patients with arterial hypertension, with or without renal involvement but without cardiac failure, the calcium values were at the lower level of the normal range Stieglitz²⁸ investigated 47 cases of pregnancy, with arterial hypertension as a secondary complication He found that the average calcium value in his pregnant patients coincided with that in his controls, and therefore he concluded that hypocalcemia is not a factor in the hypertension of pregnancy We²⁰ have reinvestigated the significance of the potassium-calcium ratio and the inorganic phosphorus, with the aid of recently devised exact methods, in 75 cases of hypertension and in 25 control cases The potassium and calcium content of the blood in patients with uncomplicated hypertension was normal In patients with cardiac complications the potassium content was somewhat high We were unable to find any correlation between the potassium-calcium ratio of the blood and hypertension Elevation of the ratio, when present, was the result of circulatory failure

Peptones Hulse and Strauss²⁹ of the Volhard Clinic have claimed that peptone-like substances in the blood of patients with hypertension caused by glomerulonephritis and eclampsia are responsible for hypertension, inasmuch as these circulating substances sensitize the effect of circulating epinephrine causing vasoconstriction This problem was again investigated at the Boston City Hospital by Jackson³⁰ who, after devising an accurate method for the determination of peptones in the blood, failed to observe any elevation in patients with hypertension

Epinephrine and Pituitrin While the aforementioned chemical theories are related to substances which can be determined chemically in the blood or the urine, the suggestion that circulating hormones, particularly epinephrine and pituitrin, are responsible for hypertension is supported by indirect evidence only. Ever since the discovery by Oliver and Schafer³¹ of the pressor effect of extracts of the medulla of the suprarenal gland, it has been suggested by Vaquez³² and other clinicians^{33, 34, 35, 36} that hyperadrenalemia is responsible for at least a certain type of hypertension. These suggestions, however, are not supported by the demonstration of an increased epinephrine content of the blood. While earlier investigators have claimed to demonstrate such an increase with biologic tests, their observations have remained unconfirmed even when such sensitive tests were applied as were claimed to give a positive reaction in a 1:700,000,000 dilution.³⁷ The comparative analysis of the adrenal gland for epinephrine also failed to yield convincing evidence that the epinephrine content of the gland from patients with hypertension differs from that in normal subjects.^{38, 39} Hence the only tangible evidence in favor of the epinephrine origin of hypertension is the apparent correlation between certain hyperplasias and tumors of the adrenal gland, and arterial hypertension. It should be remembered, however, that hyperplasia and adenoma of the cortex are frequently not associated with hypertension, but these frequent negative findings in postmortem examinations are not reported. Furthermore, no evidence exists that the cortical tissues of the adrenal gland contain vasoconstrictor substance. There are reported in the literature a few cases of tumors of the adrenal gland, partly of medullary and partly of cortical origin, which were associated with hypertension of severe and at times widely fluctuating course.^{40, 41, 42} Whether the cause of arterial hypertension in these rare instances was epinephrine, or whether the tumor and the hypertension were coincidental parts of a constitutional make-up, or, finally, whether the tumor induced certain changes in the bodily structure which then indirectly caused arterial hypertension, cannot be determined from the available evidence.

The *pituitary theory* as to the origin of certain types of hypertension has aroused much interest recently, mainly through the contributions of Anselmino^{43, 44} and Cushing^{45, 46, 47, 48}. Anselmino and Hoffmann have claimed to demonstrate that the blood and urine of women with eclampsia and arterial hypertension contain increased amounts of a substance which exerts a vasopressor and an anti-diuretic effect. These investigators have claimed that the substance is pituitrin. Recently, however, Hurwitz and Bullock⁴⁹ at the Boston Lying-In Hospital, and Page⁵⁰ at the Rockefeller Institute were unable to confirm the observations of Anselmino. In describing the syndrome of basophilic adenoma, Cushing⁴⁷ has called attention to the fact that arterial hypertension is frequently present. In support of his theory of the pituitary origin of hypertension he cites the work of Anselmino^{43, 44} and the observation of increased basophilic cells of the anterior lobe in the presence of hypertension.^{51, 52, 53} Since two groups of

investigators have failed to confirm the work of Anselmino, and since the significance of increased basophilic cells in general, and their presence in hypertension in particular, is not clear, Cushing's theory on the etiology of hypertension still lacks adequate evidence. In view of the association of basophilic adenoma with bodily changes involving different types of tissues, the interrelation between basophilic adenoma and hypertension is open to a number of other explanations than the effect of circulating pituitrin.

Increased *thyroid secretion* has also been held responsible for arterial hypertension,^{54, 55} but an examination of the data fails to reveal any direct relationship between hyperthyroidism and true arterial hypertension.

Vasoconstrictor Substances of Undetermined Nature If epinephrine, pituitrin or other substances with a vasoconstrictor effect are responsible for the development of arterial hypertension, obviously one would expect to be able to demonstrate an increased vasoconstrictor effect induced by concentrated extracts of the blood and urine. A series of such investigations has been conducted mainly by the Volhard school in recent years. Bohn and his associates^{56, 57, 58, 59} claim that extracts of the blood and urine of patients with the so-called "pale hypertension" of Volhard, which includes cases with glomerulonephritis, malignant hypertension and eclampsia, exert a marked constrictor effect on the vascular systems of rabbits and cats. Marx⁶⁰ has observed similar responses in unanesthetized dogs following the injection of extract of blood from a group of patients. Although we do not entirely agree with the rationale of Volhard's rigid classification of "pale" and "red" hypertension, nevertheless Capps, Ferris, Taylor and I⁶¹ have reinvestigated the problem of circulating vasopressor substances in the blood and particularly in the urine. We were able to demonstrate a pressor substance in the blood and in the urine in normal subjects, as well as in patients with hypertension. This vasopressor substance, however, has no relation to the degree or to the type of hypertension. In our studies, the most powerful vasopressor substances were extracted from the urine of normal subjects. It is interesting that the available evidence indicates that this *vasopressor substance* acts on the vasomotor centers and that its effect depends on the state of these centers. The work of Bohn and Marx has also been disproved recently by de Wesselow⁶² and Page.⁶³

Alcohol and Tobacco Among the exogenous chemical factors, alcohol and also tobacco have been held responsible for the development of hypertension. Without giving a detailed analysis of the literature⁶³ one may conclude that both pharmacologic and clinical evidence is lacking to support the claim that alcohol is responsible in any manner for arterial hypertension. Similarly, no convincing data are available on the etiologic influence of tobacco.⁶⁴ Although evidence is available indicating that tobacco and nicotine can induce elevation of the blood pressure in animals,^{65, 66} and that patients with arterial hypertension may exhibit accentuation of the elevation of the blood pressure during a period of excessive smoking, there are no data indicating that nicotine plays a rôle in the causation of hypertension.

The fact that a statistical analysis of the sex incidence in a large group of cases of essential hypertension at the Boston City Hospital⁶⁷ revealed a greater frequency among females may also be used as indirect evidence against the significance of alcohol and tobacco in hypertension.

Lead There is only fair evidence that lead is responsible in some instances for the development of arterial hypertension. Pharmacologic studies and clinical observation reveal clearly that lead compounds exert a constrictor effect on smooth muscles^{68, 69}. Temporary hypertension in acute poisoning, particularly during lead encephalopathy, is frequently observed. That patients who suffer from chronic lead poisoning exhibit an increased incidence of sclerosis of the arterial vessels and elevation of the blood pressure is also suggestive. The development of this true, persistent hypertension is due to a sclerosis of the vascular system^{70, 71, 72}. Obviously, however, lead explains but a small fraction of the cases of hypertension.

Thus, to summarize the results of investigators of more than two decades, while a priori the theory of the etiologic rôle of circulating vasoconstrictor substances seems plausible, actually extensive experimental and clinical studies fail to support such a contention. Lead is probably responsible for a few instances of hypertension. The correlation between certain tumors of the adrenal and pituitary glands and hypertension is suggestive, but the nature of this correlation is not known. Constitutional rather than direct hypersecretory functions are probably active. While this negative conclusion may appear to be discouraging, actually it is constructive for it allows us now to turn our attention more definitely toward other possibilities.

2 THE RÔLE OF THE NERVOUS SYSTEM IN THE CAUSATION OF HYPERTENSION

The significant rôle of the nervous mechanism in the regulation of blood pressure is well known. Although recent years have seen important progress in the field of the chemical regulation of the circulation, as well as in the field of neurochemical interrelations, today the dominant rôle of the nervous system in the regulation of blood pressure stands out even more definitely. In this nervous regulation, the sympathetic vasomotor system with its constrictor influence is a primary factor, its effect being partially inhibited by the parasympathetic vasomotor nervous system, particularly through the carotid sinus and the aortic depressor reflexes^{73, 74, 75}. The regulation of the blood pressure results through a shift of the sympathetic-parasympathetic vasomotor nervous balance owing either to decreased function of the depressor (parasympathetic) reflexes, or to increased activity of the pressor (sympathetic) reflexes. That experimental elimination of the depressor reflexes actually induces arterial hypertension has been demonstrated recently^{74, 76}.

It has been suggested, therefore, that *hypoactivity of the carotid sinus and other depressor reflexes* is responsible for arterial hypertension.

suggestion, however, based on animal experimentation, is not supported by clinical studies. If hypoactivity of the carotid sinus reflex is responsible for the development of arterial hypertension, one would expect the depressor response to be reduced or absent following stimulation of the sinus. Such is not the case in our experience, for mechanical stimulation of the sinus of patients with hypertension resulted in a relatively increased rather than in a decreased depressor response.⁷⁷ It may be contended, however, that although mechanical stimulation of the carotid sinus induces a hyperactive response under physiologic conditions, atheromatous changes in the sinuses and in the aorta may interfere with transmission of the intravascular pressure to the sensory nerve endings. Under such conditions the nerve endings may continue to respond to direct external mechanical stimulation, and yet intrasinal pressure changes would result in but slight or no reflex response. Such a suggestion of Hering⁷³ can be rejected on the basis of the careful histologic studies of Sunder-Plassmann,⁷⁸ who observed a lack of correlation between atheromatous changes in the sinus and degeneration of the nerve endings. Von Hasselbach,⁷⁹ and recently Keele,⁸⁰ found no correlation between the degree of structural change in the sinus and the aorta and the blood pressure level. In a clinical examination of the structural characteristics of the sinuses we have had similar results.^{77, 81} One may therefore conclude that studies on man do not favor the contention that hypo-function of the carotid sinus or aortic depressor reflexes is responsible for arterial hypertension. One should realize, on the other hand, that the rôle of decreased depressor reflexes requires further study.

The second possibility, namely, that an *increased pressor nervous mechanism* is responsible for arterial hypertension, is based on fair evidence. The fact that a constriction of the arteriolar system exists in hypertension is generally accepted.^{82, 83, 84} This narrowing of the arteriolar system is present in hypertension of different types, although the extent and the organ distribution may vary in the same as well as in different types of hypertension. If narrowing of the arteriolar system results from constriction of the smooth muscles, it is obviously due to increased tonus of the sympathetic system. The sympathetic system is the constrictor and the dominant portion of the vasomotor nervous system, hence variations in its tonus are to be expected. From a comparative study of a group of patients with essential hypertension and a control group, we⁸⁵ have concluded that, on the whole, the influence of the sympathetic nervous system was more pronounced and that of the parasympathetic less so in patients with hypertension than in control subjects with normal cardiovascular systems. This increased sympathetic balance was a statistical conclusion and was not present in every case. The question now arises as to the cause of this increased tonus of the sympathetic nervous system. To state, as von Monakow⁸⁶ has done, that the vasomotor center is "set" on a higher level in hypertension, is not particularly constructive in the further analysis of the problem. Bordley and Baker⁸⁷ have claimed that ischemia resulting from arteriosclerosis of the medullary

centers is a factor. Cutler's ⁸⁸ more recent study, as well as routine experiences, throws much doubt on the general rôle of medullary arteriosclerosis. That this factor, as well as local circulatory disturbances from pressure caused by tumors or other intracranial pathology, may play a rôle in some instances, seems very plausible. Studying the cerebral circulation of patients with essential hypertension, Raab ⁸⁹ in our laboratory has observed an increased oxygen difference indicating a slower blood flow through the brain. He has interpreted this finding as indicating ischemia of the cerebral circulation in hypertension. In view of the ages of the patients studied, as well as of the presence of arteriosclerosis, and because our later experience has demonstrated a more severe degree of cerebral ischemia in a number of conditions unassociated with hypertension, we cannot agree with Raab's conclusions. The ischemic etiology of the hypertonus of the vasomotor center cannot be accepted at present as the cause of hypertension.

Because patients with essential hypertension often exhibit an accentuation of the elevation of the blood pressure under *emotional stress*, and a fall during relaxation, the emotional etiology of hypertension has also received much attention. On careful examination, however, this theory does not seem to be so obvious as on first inspection. Dramatic examples of elevation of the blood pressure under stress and its fall to normal during relaxation are not lacking. Statements that patients with hypertension present a high-strung, driving personality and that hypertension is a condition of our modern age of wear and tear are also numerous in the literature ^{90, 91}. Whether vascular diseases with arterial hypertension are really modern diseases is quite doubtful. Apoplexy, heart failure of nonvalvular origin, and uremia have always been common clinical manifestations. Hypertension occurs frequently among the population of quiet, farming villages. The rôle of emotions in hypertension is not so evident in hyposensitive races as in hypersensitive and rather excitable races. Careful analytical study of the psychic make-up of hypertensive patients, including control observations, is still lacking. The difficulty of the problem is further increased by the fact that frequently during elevation of the blood pressure, changes in personality appear which are secondary to the elevation of the blood pressure ⁹². In a comparative analysis of a group of patients with essential hypertension and with normal cardiovascular systems, overexcitability, impulsiveness and a tendency to worry was, nevertheless, more frequently present in the hypertensive group ⁸⁵. In a study of 1090 ambulatory patients with essential hypertension, we ⁹³ have observed a symptomatology quite similar to that in patients with neurosis. This was also found by Davis ⁹⁴ and by Ayman and Pratt ⁹⁵. We ⁹³ have pointed out, however, that a large control group of patients with obesity and with psychoneurosis, but with normal blood pressure, exhibited the same symptomatology as patients with arterial hypertension. Thus, although psychic trauma and conflicts, as well as abnormal sensitivity of the psyche, play a rôle in essential hypertension, personality and emotional factors *alone* are not adequate in the

explanation of even a single type of hypertension. This contention is also supported by the fact that emotional disturbances in psychoses bear no relationship to the level of the blood pressure. It has been rightly emphasized by Dennig, Fischer and Beisinger⁸⁶ that no close relationship exists between "cortical" and "autonomic" functions. If, on the other hand, in hypertension a closer interrelation exists between the psychic factor and the sympathetic centers, this requires further explanation.

In addition to the suggestive central origin of essential hypertension, it is possible that pressor reflexes play an important rôle in hypertension associated with primary genito-urinary pathology.

3 THE REACTIVITY OF THE VASCULAR SYSTEM AND MECHANICAL FACTORS

As has been pointed out, an increased resistance of the arteriolar bed caused by a narrowed arteriolar system is one of the main features of the bodily state in hypertension. Such a generalized change in the arteriolar resistance is satisfactory explanation for the development of the majority of types of hypertension. One mechanism in the development of a narrowed arteriolar system, namely, increased nervous tonus, has already been discussed. A second possibility, namely, a primary cellular or mechanical origin, also merits careful consideration.

An increased constrictor response of the minute vessels to local heat and mechanical stimuli has been observed in patients with essential hypertension both by Lange⁸⁷ and in our laboratory⁸⁸. Although we do not at present possess data on the total transectional area of the arteriolar system, clinical and postmortem experiences reveal variations in the arterial lumen in different subjects. At times the narrowed state of the vascular system of women in good health, who later develop hypertension during pregnancy, is striking. It is also established that with advancing age there is progressive accumulation of intercellular cement substances, loss of elasticity of tissues, arteriosclerotic and other involutionary changes which are all included in the collective term of "changes of senescence". These changes result in the shrinkage of the lumen of the small arterial vessels and in a secondary progressive rise in blood pressure. A moderate degree of progressive rise is thus an expression of physiologic senescence. In persons with congenitally hypoplastic arterial systems, however, the normal changes of senescence result in a marked increase in the vascular resistance. In persons with increased severity of degenerative changes an increased arteriolar resistance also develops. That mechanical factors of increased peripheral resistance play a role in arterial hypertension is demonstrated by cases of coarctation of the aorta, in which elevation of the blood pressure exists in vascular areas originating from portions of the aorta in front of the resistance, and by cases of obesity in which the hypertension may completely disappear with reduction of body weight. The fact that a sudden rise in

the incidence of hypertension coincides with the age of onset of involutionary changes of the body in each sex, also supports this view⁶⁷ Thus in a study of the age distribution of 1620 ambulatory patients with hypertension, the bulk of the cases were noted after the age of 40, coinciding with the onset of involutionary changes, such as climacteric, and not in youth when the sensitivity of the nervous system is greatest and when mild, temporary emotional hypertension is relatively common^{68, 69} The finer mechanism through which a primary generalized increased arteriolar resistance of nervous, cellular or other origin results in an increased cardiac force and hence in hypertension, is not clear It has been suggested that with the increased arteriolar resistance as the result of local ischemia, tissue metabolites stimulate efferent nerve endings of a widespread cardiopressor reflex¹⁰⁰

It has also been claimed recently that in certain types of essential hypertension, in addition to changes in the minute vessels there is a progressive loss of elasticity and of the propulsive action of the aorta and other large vessels^{101, 102, 103} The decreased elasticity of these large arteries also explains the relatively high systolic pressure and the high pulse pressure without increased cardiac output which were observed by us recently⁸¹ This pertinent problem, particularly as to whether changes in the arteries occur early or only in the later stage, merits further investigation

The mechanical theory that hypertension of nephritis is due to local vascular resistance of the kidneys, first proposed by Traube,¹⁰⁴ is not tenable, both because of theoretical objections and because our studies of the hemodynamics of the circulation in hypertension of nephritic origin reveal a widespread vasoconstriction⁸³ That local disturbance of the renal circulation can induce experimental hypertension, on the other hand, has been shown repeatedly Such an experimental hypertension has been induced by excising varying amounts of kidney tissue,^{105, 106, 107, 108, 109} by damaging the kidney with roentgen-rays,¹¹⁰ by local renal venous stasis,^{111, 112, 113} and recently by progressive clamping of the renal arteries¹¹⁴ Fahr¹¹⁵ maintains that renal ischemia plays a rôle in the induction of hypertension associated with nephrosclerosis There are, indeed, a number of clinical examples indicating that local diseases of the genito-urinary tract are followed by arterial hypertension The explanation of hypertension of kidney and genito-urinary system origin does not lie in increased local vascular resistance but, as has been pointed out recently by Goldblatt, Lynch, Hanzal and Summerville,¹¹⁴ is based on one or more of the following possibilities (a) afferent impulses are set up from the affected nerve endings in the ischemic kidneys to the vasomotor centers, whence a general vasoconstriction is induced, (b) afferent impulses from the ischemic kidney may influence some internal secretory gland, and (c) there may be an accumulation or new formation of some substance or substances which, after entering the blood stream, induce a general vasoconstriction At present the exact mechanism of hypertension induced from the kidney and urinary passages is not known

4 THE RÔLE OF INFECTIONS AND VASCULAR ALLERGY

Evidence that infections play a direct etiologic rôle in the *majority* of instances of hypertension is lacking. Clinical observations, on the other hand, furnish ample evidence indicating an indirect etiologic rôle for infections. There is not a single type of infectious agent which is regularly associated with hypertension. The majority of infections associated with hypertension first produce kidney lesions, and hypertension then develops as a secondary manifestation. In this sense, streptococci are indirectly responsible for certain cases of hypertension. Similarly, urinary infections of childhood with pyelonephritis, or with partial stricture of the ureter, cause hypertension, which at times imitates the clinical picture of essential hypertension. The hypertension of mitral stenosis¹¹⁶ also represents such an indirect relationship. The apparent relationship between syphilitic aortitis and hypertension¹¹⁷ can be explained by changes in the aorta and particularly by narrowing of the lumen of arterial openings.

The claim that allergy plays a role in arterial hypertension^{118, 119} cannot be accepted as yet. In certain cases of malignant hypertension, particularly in periarteritis nodosa, infections such as peridental abscess, pyelitis, perinephritic abscess, seem to play an indirect rôle. The problem of vascular allergy has not been investigated with the care it deserves.

5 CONSTITUTION AND ARTERIAL HYPERTENSION

In the foregoing discussion we have concluded that vascular changes of senescence, local irritability of the vascular tissues, psychic factors, increased tonus of the autonomic nervous system, increased pressor reflexes, infections and lead play a rôle in the development of various types of arterial hypertension. It should be emphasized, however, that any of these factors may be present in even greater intensity in persons with normal blood pressure. Thus, although the rôle of the above factors stands out clearly, their relation to hypertension is not a direct and consistent one. The postulation, therefore, of an added factor seems inevitable. One may state with justification that these etiologic agents result in hypertension only if they act on persons with a certain psychophysical make-up. The fact that extensive investigations have failed to reveal any single factor which regularly causes arterial hypertension, strengthens the importance of the rôle of the constitution.

Detailed knowledge of this constitution is still lacking. It is probable that the physical aspect of the body habitus is the least important. Weitz,^{120, 121} de Nador-Nikitits¹²² and others deny that the sthenic habitus (megalosplanchnic habitus of Viola or pyknic of Kretschmer) has a special relation to hypertension. Daily clinical experience, also, suggests that among patients with pronounced hypertension all types of bodily habitus occur with approximately the same frequency. It is suggestive, then, that an understanding of the inherited anatomic and functional characteristics of the nervous and

vascular systems rather than the bodily habitus will eventually bring the solution. It is known that the vascular and nervous systems are particularly apt to transmit constitutional stigmata. Striking examples of a hereditary history in hypertension, nephritis, and cerebral vascular accidents have been known to clinicians ever since Forestus in the sixteenth century called attention to the hereditary occurrence of apoplexy.

O'Hare, Walker and Vickers¹²⁴ elicited a family history of vascular disease in 68 per cent of a group of patients with arterial hypertension. On the basis of an extensive study Weitz^{120, 121} concluded that hypertension is inherited as a dominant characteristic. Recently Ayman¹²⁵ has presented additional data on the rôle of heredity. The fact that a hereditary history cannot be obtained in a higher percentage of cases is natural, and does not invalidate the significant rôle of the constitution, for a hereditary history is but partial and rather crude evidence of hereditary constitution, and just as the dividing line between what constitutes a normal person and one with hypertension is ill-defined, so is there no hard and fast division between the constitutional characteristics possessed by the two types.

COMMENT

In a consideration of the pathogenesis of hypertension, the general nature of the problem must be viewed as a whole. Just as before the discovery of insulin it was of aid in research to consider diabetes mellitus as a disease caused by disturbed function of the islands of Langerhans, and hence primarily a deficiency disease, so it is equally important to appreciate that arterial hypertension is not a disease entity but a bodily state of multiple etiology. We use the term "arterial hypertension" only because we can measure conveniently an important aspect of the circulation. The alteration in the blood pressure, however, is not the primary, nor even the most important, aspect of the problem. Change in the minute arterial vessels, which we cannot measure at present, is the primary site of the vascular change. Not only is the character of these vascular changes varied, but the same type of change, such as diffuse arteriolar spasm, is induced by different etiologic factors.

In taking the level of the blood pressure as an index of peripheral vascular changes, we have selected a circulatory function which undergoes considerable variation even in health, for in the homeostasis of the body arterial tension is not a rigid constant, when compared with body temperature and chemical regulation of the blood. Hence, we are quite arbitrary in considering a systolic pressure of 145 mm Hg "normal" and a pressure of 155 "hypertension." The transition from a normal to hypertensive state is very gradual. In the majority of instances of hypertension we are dealing with but a moderate accentuation of the physiologic factors. Experience, on the other hand, has taught us that patients with markedly

elevated blood pressure frequently exhibit functional and structural disturbances of various organs, hence the clinical emphasis on the problem of hypertension is justified

In spite of numerous investigations with negative results and faulty conclusions, the labor of the past two decades has resulted in remarkable progress in this important and difficult field. The fact that we have put suggestions and theories to the acid test of experimental research in itself represents a great advance. Much is known today of the hemodynamics and the vascular state in arterial hypertension. We have appreciably clarified the reversible interrelation between hypertension and kidney pathology. We have also definitely ruled out the suggestion that alterations in the cardiac output, stroke volume, blood volume, or viscosity of the blood are primary factors in the pathogenesis of the disease. On having established the significance of the stenotic state of the arteriolar system and of diminished elasticity of the larger arteries, today we are permitted to turn our efforts toward the primary etiologic mechanisms. Much is yet to be learned concerning this aspect of the problem. The fact, however, that extensive and painstaking search has failed to reveal any single factor of chemical or nervous nature which specifically and regularly induces hypertension seems to us very significant. It suggests that we may be dealing with a condition of multiple rather than of single etiology. Perhaps success in unfolding the nature of diseases of primary or of single etiology has wrongly trained us in the past half century to search always for a single cause of a disease.

From the above presentation it is clear that a number of factors definitely bear on the etiology of hypertension. It was emphasized that the factor or factors which are definitely active in a given case may not be present in all cases of the same type of hypertension, and furthermore the factors responsible in hypertension may occur in subjects with normal blood pressure. We wish to emphasize that this apparent contradiction does not obviate the rôle of these factors, but it suggests a special "affinity" or "susceptibility" on the part of the patient for these precipitating factors. Physiologic examples in human beings are numerous showing that an identical nervous or chemical stimulus exerts its effect on different organs in different groups of subjects.¹²⁶ Thus in the study of the etiology of arterial hypertension we should always analyze the primary constitutional characteristics of the patient, as well as the secondary precipitating factors. Today suggestive experimental and clinical evidence is available indicating that the role of inheritance and constitutional predisposition are represented mainly by inherited and at times acquired local irritability of the minute vessels, hyperirritability of the sympathetic vasomotor centers, and hypoplastic development of the vascular system. Among the secondary factors acting on such constitutionally susceptible nervous and vascular systems are emotional stress, physiologic changes of involution and senescence, obesity, certain types of infections, reflexes, particularly from the genito-urinary organs, and a few exogenous chemical substances. The relative rôle of

these factors varies considerably. The present evidence indicates that in the great majority of instances involutionary and senescent changes are active in the constitutionally predisposed individuals. The present classification of primary or essential (benign and malignant) and secondary hypertension of kidney origin indicates mainly the clinical and morphologic state of the body, but does not correspond to a single characteristic etiology.

The interpretation of hypertension as given here carries with it a certain amount of argument against the possible effectiveness of drugs, serologic or substitutional therapy. It implies that prevention and elimination of the secondary precipitating factors represent the main approach in treatment. While such a belief may seem pessimistic, since it eliminates at once the rationale of a search for a "cure," it is, nevertheless, in accordance with clinical experience, and furthermore emphasizes the rôle of physicians as advisors of patients rather than as dispensers of medication.

INFLUENTIAL FACTORS IN RECOVERY FROM RHEUMATOID ARTHRITIS^{*}

By RUSSELL L. CECIL, M.D., F.A.C.P., *New York, N. Y.*

EVERY physician knows that there is more than one factor which enters into recovery from an infectious disease. These various factors are constitutional or environmental. It occurred to me that it might be interesting to consider at this time the more important factors which influence recovery in one of our commoner infections, namely rheumatoid arthritis. At the outset some may object to the assumption that rheumatoid arthritis is a chronic infection. It must be admitted that the evidence for its infectious nature is not complete, but the fact remains that the majority of investigators in this field now consider it a chronic infection, and the writer will therefore discuss the disease from the infectious point of view in the present paper.

Any kind of discussion of rheumatoid arthritis is always handicapped by the fact that we know so little concerning the origin and nature of the disease. In observing a patient with rheumatoid arthritis we see pathologic changes and symptoms which bear all the earmarks of a chronic infection. But just *why* the patient develops the disease, or exactly *how* he develops it are still subjects for speculation. This, of course, is true of other infections which are better understood than rheumatoid arthritis. "First causes" in medicine are always problematical. Let us, therefore, concern ourselves no longer with the teleology of this disease, but proceed at once to a discussion of the factors which influence, or appear to influence, recovery from it.

CONSTITUTION

We can do no better than begin with constitution. Is there such a thing as a constitutional diathesis toward rheumatoid arthritis? The writer believes that there is. I have seen too many long lanky men and women with the disease to question the tendency of this type toward rheumatoid infection. This of course is the so-called tuberculous type and raises the question whether there is any basis for the contention now being made by certain German writers that rheumatoid arthritis is a form of tuberculosis. One sees stocky, and even obese, patients in an arthritis clinic, but most of them are suffering from hypertrophic rather than from rheumatoid arthritis, and many of the rheumatoid patients who appear rotund have been slender and long-trunked in their younger days. I would not deny, of course, that the stocky, so-called brachycephalic type can develop rheumatoid arthritis, but I think it is an exception to the rule, and I am quite sure that the stocky type responds more readily to treatment than do the dolichocephalics.

^{*} Read at the Chicago meeting of the American College of Physicians, April 19, 1934.

TEMPERAMENT

Closely allied to constitution is the question of temperament. Neurotic, introspective patients are more difficult to relieve than buoyant cheerful ones. The natural melancholy of the Jewish race has always seemed to me a distinct handicap to their recovery from rheumatoid arthritis, though here again there are many exceptions. I have often wondered why so many spinsters develop the rheumatoid syndrome. I doubt if the sex hormones are influential in this connection. It appears more likely that the really predisposing factor is the temperament of the patient.

HEREDITY

There is great need for a thorough-going, scientific study of heredity in relation to rheumatoid arthritis. There are very few articles on this subject in medical literature. Marinesco and Allende¹ have recently reported the cases of two brothers and a sister, all of whom developed in the early years of their childhood the deforming type of chronic infectious arthritis, so-called Still's disease. The writer recalls from his own experience two families in which the incidence of rheumatoid arthritis was amazingly high. In one of these families the disease could be accurately traced through four generations (Table 1). Such extreme examples are unusual, but the hereditary factor may be more important than we have realized. Certainly a great many of the writer's patients testify that one or both of their parents suffered from chronic arthritis. The difficulty arises in determining what type of arthritis the parent had—that is, whether it was rheumatoid or hypertrophic in character. Some of our young students of arthritis could hardly find a more interesting problem for investigation than the rôle of heredity in rheumatoid arthritis. I should add that in those cases where heredity appears to play an important part, the patient often progresses to the deforming and ankylosing stage of the disease in spite of all treatment.

RACE

So far as the writer knows, no race is immune to rheumatoid arthritis. I suspect that the dark races are less susceptible than the white races, but this may be due to differences of habits or environment rather than to any variations in racial immunity.

AGE

Rheumatoid arthritis may develop at any age and may be a formidable menace to health at any age. Cecil and Archer² found the highest incidence of onset was at 35. So far as recovery is concerned, I used to think that young adults offered a better prognosis than patients who developed the syndrome late in life. With increasing experience, however, I am not so

thoroughly convinced on this point I have recently seen several patients who developed rheumatoid arthritis after 60, and who have responded promptly to treatment Tuberculosis is supposed to deal more kindly with the middle-aged and elderly than with young adults, and the same may be true of rheumatoid arthritis This point can be settled only by careful statistical studies Middle-aged and elderly patients are more cooperative than young people and follow the physician's instructions more carefully On the other hand, they often have to contend with a coexisting osteoarthritis, which may set up a sort of vicious circle in the joints affected

SEX

I am sorry to say that I have no figures on the incidence of recovery from rheumatoid arthritis with respect to sex We do know that women are two or three times as susceptible to the disease as are men, and my impression is that in general men respond more quickly to treatment than do women

CLIMATE

The final chapter on the relation of climate to the incidence of rheumatoid arthritis and to recovery from this disease has yet to be written It is claimed, and I suspect rightly, that the natives of Arizona and New Mexico never develop rheumatoid arthritis It is rarely seen in the tropics, though I believe it is fairly common in some of our southern cities, such as New Orleans Certainly it is commoner in the southern part of the United States than rheumatic fever We have yet to determine, however, just how much better the prognosis of the rheumatoid patient is in Arizona than it is in the eastern part of the United States, assuming that the other environmental factors are the same What I mean to say is this How much higher is the percentage of recovery for arthritic patients in an Arizona sanatorium than it would be for patients in a New York or Pennsylvania sanatorium? This question can be answered only by carefully prepared statistical and follow-up studies Theoretically Arizona, because of its wonderful climate, should have the best of it, but unfortunately even Arizona fails with many of our more stubborn cases

ECONOMIC STATUS

Rheumatoid arthritis is like tuberculosis and rheumatic fever It is more prevalent among the poor than among the well-to-do, and the former do not respond so well to treatment The poor are more exposed to cold and damp weather, their food is not so well cooked, their diet often poorly balanced They have not the means of getting proper medical attention, and more important still, they have not the time or money for rest cures

JOINTS INVOLVED

The outcome in rheumatoid arthritis depends to some extent on the joints involved. When the fingers are first attacked it often seems to confer some immunity against involvement of the larger joints. The knees are bad joints mechanically and always present a difficult problem, not only because of the intricacy and size of the joint, but because it is a weight-bearing joint. I have often noticed that in convalescent patients the knees and feet will be the last to recover, usually because the patient becomes restless, discontinues rest and starts walking before the joints have healed completely. The hip is usually one of the last joints to be affected in rheumatoid arthritis, and this is indeed fortunate, because infection of the hip joint is painful and yields very slowly to treatment.

Perhaps the most stubborn of all is the infectious spondylitis of the Marie-Strumpell type. "Poker spine" is a hard disease to check. It occurs almost exclusively in young males and often runs a rapidly progressive course, producing marked rigidity of the spine and ankylosis of the shoulders and hips.

EFFECT OF OTHER DISEASES ON DEVELOPMENT AND COURSE OF RHEUMATOID ARTHRITIS

I have recently become interested in investigating the effect of other diseases on the incidence and course of rheumatoid arthritis.

Focal Infection I suppose no one would deny the importance of focal infection in the etiology and course of rheumatoid arthritis. The fact that the removal of foci of infection does not always lead to recovery from arthritis detracts in no way from its significance. A great many people carry foci of infection for years without any joint symptoms. A certain number will develop arthritis. Why some get the disease and others escape, we do not know, but we cannot avoid the conclusion that focal infection is an important predisposing factor in the etiology of rheumatoid arthritis and that the elimination of such foci is a fundamental step on the road to recovery.

Pulmonary Tuberculosis Rheumatoid arthritis is comparatively rare in tuberculous patients. Pemberton³ is my authority for this statement, which is in agreement with my own personal experience. The two diseases do occur, however, in the same patient as the following example will show.

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Pulmonary Tuberculosis

R H Female Aged 26

| | |
|------|--|
| July | 1930—Migratory progressive pain and swelling of joints |
| Nov | 1930—Hemorrhage Diagnosis Pulmonary tuberculosis |

- Summer, 1931—Saranac "Extensive pulmonary tuberculosis" Pain and swelling of joints
- 1932 to 1933—At Saranac Marked improvement in both conditions Became practically free of symptoms
- May 1933—Return of pain and swelling of joints
Rales at left apex
Agglutination *Streptococcus hemolyticus* 1 320 Sedimentation rate 13 WBC 8,000 Tonsils out Vaccine, etc
- March 1934—No signs of tuberculosis Practically free of joint symptoms

The arthritis in this case never presented the picture of a tuberculous infection Furthermore the agglutinins for *Streptococcus hemolyticus* in the patient's serum identified the disease as rheumatoid arthritis

Syphilis When chronic arthritis develops in a syphilitic patient, one must be sure that he is not dealing with a syphilitic arthritis This differentiation, however, is usually easy as luetic arthritis, like tuberculous arthritis, usually involves only one joint The following case presented all the symptoms and signs of rheumatoid arthritis and occurred in a patient with a strongly positive Wassermann

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Syphilis

G D Female Aged 44

1925—Onset of rheumatoid arthritis

April 1930—First seen by writer Mild rheumatoid arthritis Chronic sinusitis
Several fusiform fingers Agglutination *Streptococcus hemolyticus*
1 1280

April 1931—No improvement after one year of routine treatment
Wassermann 4 plus (controlled)
Husband 4 plus
Salvarsan and bismuth

Oct 1931—Rapid disappearance of all arthritic symptoms

The improvement in the arthritis was so marked after the introduction of specific therapy that one might have suspected this of being a luetic arthritis but for the high agglutination with *Streptococcus hemolyticus* The chronic focus in the sinus and the typical fusiform fingers also supported the diagnosis of rheumatoid arthritis It seems fair to assume that in this case rheumatoid arthritis developed in a patient whose resistance had been lowered by a previous luetic infection and that when the latter was brought under control by specific therapy, the patient soon got control also of the arthritic condition We might also suspect that in this case the arsenic in the salvarsan was of distinct benefit to the arthritic as well as to the syphilitic infection

Rheumatic Fever It would not be appropriate in this discussion to take up the relationship of rheumatic fever to rheumatoid arthritis This question has recently been discussed at length by Dawson,⁴ who believes that the two diseases are very similar in character We do know that a few

cases of rheumatic fever progress into a condition indistinguishable from rheumatoid arthritis I can recall one young man in my own practice who, subsequent to rheumatic fever, developed rheumatoid arthritis and, after suffering with it for two or three years, finally made a complete recovery His only residual lesion was a severe mitral endocarditis

Gout The etiology of gout is still a subject of much debate Some writers speak of it as a metabolic disease Others consider it an allergic condition, and still others an infection The writer is quite sure that on more than one occasion he has encountered rheumatoid arthritis and gout in the same patient The following two cases will serve as good examples

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Gout

J W Male Aged 39

- 1913—Acute gout in great toe
 1913 to 1928—Sporadic attacks in right great toe Becoming more frequent
 1928 to 1932—Attacks of polyarthritis
 June 23, 1932—First seen by writer Chronic podagra Arthritis of ankles and knuckles Fusiform joint, left ring finger Uric acid 6.5 mg
 Agglutination *Streptococcus hemolyticus* 1:2560
Streptococcus hemolyticus 3 plus positive in throat culture
 July 26, 1933—Much improved after a year of treatment Agglutination *Streptococcus hemolyticus* neg Uric acid 4.3 mg
 1933 to 1934—Occasional attacks of gout, but arthritis no longer active

This patient undoubtedly had gout, and the high agglutination with the *Streptococcus hemolyticus* pointed strongly toward a concomitant rheumatoid arthritis The swelling and pain in various joints and the fusiform ring finger were also strongly indicative of rheumatoid arthritis

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Gout

R S R Male Aged 51

- July 1931—Progressive polyarthritis with swelling, fusiform fingers, etc
 Jan 1932—First seen by writer Typical rheumatoid arthritis Agglutination *Streptococcus hemolyticus* neg Sedimentation rate 12 mm Uric acid 4.2 mg
 April 1933—Arthritis much improved Fusiform fingers almost disappeared Sedimentation rate 15 mm
 Sept 1933—Arthritis much improved, but patient has developed typical gouty bursitis on both elbows Colchicum, atophan, etc Uric acid 5.1 mg
 Jan 1934—Feeling fine, gaining weight "Bags" on elbows much smaller Sedimentation rate 0.8 mm Uric acid 3.7 mg
 April 1934—Relapse Pain and swelling in toes, elbows and right hip Sedimentation rate 16 mm Uric acid 5.0 mg

This patient is still under observation He is slowly recovering from

a severe joint condition, one which I and others thought would surely result in permanent crippling

Pernicious Anemia The writer has no very definite impressions concerning the effect of a coincident pernicious anemia on the course of rheumatoid arthritis. An appeal to my friend, Dr George Minot,⁵ brought the following interesting reply, which I have his permission to quote

The patient was a woman of about 60 years of age with typical pernicious anemia, whom I had suspected of having pernicious anemia several years before treatment was begun. Typical rheumatoid arthritis had existed for at least five years in a mild form. Under treatment with liver extract, the blood picture returned to normal. About the time the blood became normal, there was a sharp exacerbation in the rheumatoid arthritis. During the period of improvement her appetite was vastly better than it had been for many years, and she gained a moderate amount of weight. For the flare-up in her arthritis a rest program and a diet containing fewer calories were prescribed. After approximately six months the rheumatoid arthritis had lost its intensity and she was definitely better. At a later date this patient gave up liver, of her own accord, and relapsed. The arthritis remained quiescent, but increased in intensity as she got better again. This all happened over four years ago. I saw her about four months ago and she has remained in good health.

On the contrary, there are other cases I can cite where practically the reverse state of affairs took place. One was a female 40 years old. Arthritis in this instance was the presenting symptomatology of long duration, certainly five years. The anemia developed slowly, at first it was thought to be hypochromic, examination, however, showed it to be macrocytic. Tongue symptoms appeared. Increased rheumatoid arthritis was obvious at the time the blood was low (approximately two million red cells per cu mm) and in this instance, coincident with return of the blood to normal, the arthritis improved pronouncedly. In this latter case the individual was definitely under-weight, in the former case the patient was a little over-weight, even during the relapse in pernicious anemia.

Dr Minot feels as I do, that without many more case studies, we can say nothing definite about the relation between these two diseases.

Psoriasis The frequent coexistence of psoriasis and rheumatoid arthritis has long been a subject for comment. The writer has the impression (which, however, is not based on statistics) that few if any of the arthritics with psoriasis ever make a complete and permanent cure of either disease, though they may improve under treatment. In the German and French literature this syndrome is spoken of as *arthritis psoriatica*. Bauer and Vogl⁶ showed that in certain families, some members were suffering from psoriasis only, some from a polyarthritis only, while some presented the combined syndrome. They further claim that different types of joint diseases are to be met with in patients suffering from psoriasis, though they admit that the arthritis is usually of the chronic infectious or rheumatoid type. In one family Bauer and Vogl encountered an intermittent hydrops in association with psoriasis. Several other members of the family also had psoriasis and one of these suffered in addition from rheumatoid arthritis.

The following two synopses are taken from my own case records

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Psoriasis

J M Female Aged 25 Psoriasis since age of 7

| | |
|-------|--|
| | 1918—Gradual onset of rheumatoid arthritis |
| Oct | 1927—Severe rheumatoid arthritis Psoriasis all over body |
| Nov | 1927—Tonsillectomy, streptococcus vaccine, etc |
| Jan | 1928—Joints improving Psoriasis better |
| Sept | 1928—Recurrence of arthritis Return of psoriasis |
| Jan | 1929—Feeling fine Slight improvement in psoriasis |
| April | 1929—Some pain in joints Increase in psoriasis |
| Dec | 1929—Return of symptoms in joints and more psoriasis |
| Dec | 1930—Pain in back and joints Psoriasis troublesome |
| Jan | 1931—Joints comfortable Much less psoriasis |
| March | 1934—Arthritis much improved Psoriasis persists |

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Psoriasis

A T Male Aged 47

| | |
|--------------|--|
| | 1915—Gradual development of rheumatoid arthritis Psoriasis appeared about same time |
| 1924 to 1926 | —Almost free of symptoms "Psoriasis always better when joints are better" |
| | 1927—Return of arthritis |
| Jan | 1931—First seen by writer Extensive rheumatoid arthritis Spots of psoriasis all over body Streptococcus vaccine intravenously, diet, etc |
| March | 1931—Much improved Psoriasis fading Scales disappearing |
| April | 1931—Steady improvement in joints and in psoriasis |
| Sept | 1931—Practically free of symptoms Psoriasis almost gone |

These two case histories illustrate a fact that I have long recognized, namely that arthritis and psoriasis improve or regress together I have seen a good many patients with rheumatoid arthritis and psoriasis, and I feel moderately certain that when one condition improves, the other improves

Hyperthyroidism A good deal has been written about the relation of arthritis to the thyroid gland, but there is no convincing proof of any connection between the two The following case, however, has certain points of interest

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Hyperthyroidism

W J Male Aged 29

| | |
|------|---|
| May | 1929—Onset of rheumatoid arthritis |
| Jan | 1930—Sinus operation Rest in hospital 2 months Florida 2 months |
| June | 1930—Returned to work |
| Aug | 1930—Relapse |
| Oct | 1930—First seen by writer Severe rheumatoid arthritis and spondylitis Agglutination <i>Streptococcus hemolyticus</i> 1 160, |

Nov 1930—Tucson
 Dec 1930—B M plus 35 (controlled) Weight 92 lbs
 Feb 1931—Thyroidectomy
 Dec 1931—Remarkable and complete recovery except for some residual stiffness in spine

The improvement in this patient's condition following thyroidectomy was quite remarkable. One would expect a priori that a high basal metabolism would react favorably in a patient with rheumatoid arthritis. Indeed, thyroid extract has been recommended by more than one authority as a valuable agent in the treatment of rheumatoid arthritis. In this particular case, however, the arthritis progressed unfavorably in spite of all treatment until the metabolism was brought back to normal by thyroidectomy.

Diabetes Diabetes is a much commoner associate of hypertrophic arthritis than it is of the rheumatoid type. The coexistence of diabetes with rheumatoid arthritis is of particular interest in view of Pemberton's⁷ claims that the sugar tolerance is low in this form of joint disease. The following case illustrates the coincidence of diabetes and rheumatoid arthritis.

CASE REPORT (ABSTRACT)

Rheumatoid Arthritis and Diabetes

W L Male Aged 54

1925—Chronic sore throat Onset of diabetes 20 units of insulin daily
 1926—Gradual development of pain in knees and feet
 Jan 1930—Rapid onset of rheumatoid arthritis affecting many joints
 May 9, 1930—First seen by writer Many joints swollen Blood sugar 238 mg
 Urine showed trace of sugar
 June 6, 1930—Treatment for arthritis started vaccine, diet, etc
 June 13, 1930—Tonsils removed
 July 15, 1930—Joint condition improving steadily Blood sugar 200 mg Urine free from sugar
 Aug 6, 1930—Joints continue to improve Goes on a vacation
 November 1930—Patient died suddenly, cause unknown

TREATMENT

No discussion of the factors influencing recovery from rheumatoid arthritis would be complete without some consideration of the method of treating the disease. The method of treatment varies a great deal in different localities, and it would be beyond the scope of this article to discuss in detail these various methods of treating rheumatoid arthritis. There are certain fundamental phases of the treatment, however, that have an important influence on the course of the disease.

For example, with regard to foci of infection. A good deal depends upon *when* and *how* the focus in question is removed. For example, a focus removed early in the disease often leads to a permanent recovery from

the arthritis, while one removed two or more years after the onset of the joint symptoms rarely produces a favorable effect on the disease. Then so much depends on *how* foci are removed. The writer could cite more than one instance of sharp exacerbation of joint symptoms following tonsillectomy by an inexperienced or unskillful operator. I know of no operation where gentle handling of the infected tissue is more important. On the other hand I could cite one or two laryngologists who so far as I know have never produced a flare-up in an arthritic patient after the removal of tonsils. This has convinced me that good results following tonsillectomy depend a great deal on who removes the tonsils. Perhaps what has been said about tonsils applies even more in the case of surgery of the sinuses. Operations on the ethmoid and sphenoid cells are difficult at best and certainly require the utmost skill on the part of the operator if good drainage is to be established. In patients who have multiple root abscesses, it is better not to extract all the infected teeth at one sitting. Exacerbations in the joints have been known to follow such radical treatment.

If space permitted, a great deal could be said about the importance of cooperation on the part of the patient, and also concerning the choice of a physician. I would like to say one thing about the latter. I am not very sympathetic with the so-called arthritis specialist, that is, with the practitioner who devotes himself exclusively to treating this one disease. He will probably give his patients better treatment if he is a good all-round internist. I do say, however, that the patient with arthritis is wise if he seeks the counsel of a physician who is interested in this disease. The treatment of chronic arthritis, like that of the other great systemic diseases, presents a complex medical problem, and with it go the various specialized forms of therapy, such as control of diet, physiotherapy, intravenous vaccines, orthopedic measures, etc. Personally I believe that the time is not far off when every state in the Union will have specially equipped sanatoriums for the treatment of arthritis, similar to those which now exist for the treatment of tuberculosis. When that day comes, it is reasonable to believe that the chronic arthritic will fare much better than he does at present.

SUMMARY

In this brief discussion, I have tried to sum up the various factors which predispose to, and influence the course of, rheumatoid arthritis. We have seen that these factors may be either constitutional, such as race, temperament, heredity, sex, age or some constitutional disease, or they may be entirely environmental, depending on the economic status of the patient, his place of abode, the type of doctor he selects, and the kind of treatment he receives.

When we consider the multiplicity of factors which enter into recovery from this baffling disease, the need of concentrated and specialized care for rheumatoid patients becomes all the more obvious. In the opinion of the

writer, a considerable proportion of them should be treated in sanatoria especially equipped for the care of rheumatoid cases

CARDIOVASCULAR OBSERVATIONS IN 215 NEUROSYPHILITICS *

By CLOUGH TURRILL BURNETT, M D, F A C P, and CHARLES A
RYMER, M D, *Denver, Colorado*

THE subject of this paper, cardiovascular syphilis, offers an interesting example of a tendency to search for the new while at times forgetting the old teachings. Aortic aneurysm appears after the introduction of syphilis into Europe subsequent to the return of Columbus and the occupation of Naples by the army of Charles VIII in 1495. Some sort of association with syphilis was mentioned by Fernelius in 1542, by Vesalius in 1557, and by Paré in 1582, who associated aneurysm with the "French disease." Morgagni (1682-1771) noted the association of aortic disease with syphilis. He first described a case of heart-block and what was later known as the Stokes-Adams syndrome. Then the luetic origin of aortic aneurysm was forgotten until nearly the middle of the past century, although Osler states that syphilis of the heart was mentioned as far back as 1736. French writers claim that Ricord, who was American born, first described definite cardiac gumma in 1845. However, accurate knowledge of cardiovascular syphilis is but little more than 50 years old, and 20 years ago there was practically no mention of the subject in current textbooks. There appears to have been a definite increase since the war and, either because of this or improved methods of diagnosis, it has occupied an important place in recent medical literature †

FREQUENCY OF CARDIOVASCULAR SYPHILIS

Numerous authors have discussed this subject with a wide divergence of opinion. The relation of cardiovascular syphilis to all forms of heart disease is given by Coombs¹ as 5 to 15 per cent and by Moore, Dangle and Reisinger² as 10 to 15 per cent. In general autopsy statistics cardiovascular syphilis appears according to different observers in 2 to 6 per cent of the cases examined. Aortic syphilis was observed at autopsy in late syphilis in 20.5 per cent of the cases examined by Coombs¹. Moore and his associates³ quote Langer, of Germany, to the effect that 70 to 80 per cent of all syphilitics show aortitis, aortic insufficiency or aneurysm, and that 50 per cent of all aortic insufficiency is syphilitic. Moore also advances the opinion that 80 to 90 per cent of all late syphilitics show evidence of aortic syphilis. Warthin^{4, 5, 6} teaches that aortitis with aneurysm or aortic insufficiency occurs in some degree in the aorta of every male syphilitic and,

* Read at the Chicago meeting of the American College of Physicians, April 19, 1934.
From the Psychopathic Hospital and Department of Medicine of the University of Colorado School of Medicine and Hospitals, Denver.

† Since this was written, a most comprehensive review of the literature on cardiovascular syphilis has been presented by Dr. Lewis A. Conner in the Jr. Am. Med. Assoc., 1934, cii, 575, to which those interested are referred.

considering this frequency, that aneurysm and aortic insufficiency are rare occurrences in the history of aortic syphilis, and that these when present are due to functional stress. A more startling statement of the same author is as to the occurrence of syphilitic involvement of the heart. Briefly, this is that the spirochete is constantly present in the heart muscle of all cases of latent syphilis. In the congenital syphilitic heart the spirochete is demonstrated with some facility, but in the acquired form, while he states that the spirochete is constantly present, the demonstration of these organisms may require the utmost patience and considerable time—often weeks. Friedman⁷ quotes numerous authors as showing that vascular changes are noted in from 49 to 76 per cent of cases of visceral syphilis. The per cent in which thoracic aneurysm is syphilitic is given by Coombs¹ and Lendon⁸ as 75, and of abdominal aneurysm 35 by the former and 33.3 by the latter author. Moore and his coworkers³ state that 10 per cent of tertiary syphilitics show cardiovascular syphilis clinically but only 3.8 per cent of the cases of uncomplicated aortitis were correctly diagnosed antemortem, while according to Jagic⁹ only 2 per cent were clinically diagnosable. Grassman, quoted by Turner and White,¹⁰ found that in 288 cases of secondary syphilis arrhythmias or pulse disturbances were noted in 85 per cent and murmurs in 40 per cent. Amelung and Steinberg¹⁰ believe the above figures too high. They studied 275 early cases for one year and noted heart enlargement (confirmed by roentgen-ray), sound changes, tachycardia, premature contractions or murmurs, in 21 per cent. In this group was one case of aortic insufficiency, which was recognized clinically, and two proved at autopsy. Brooks¹¹ reports 2 cases of aortic aneurysm within six months of the primary lesion, and has in another report¹² recorded 24 of 300 cases of cardiac lues occurring in the secondary stage. Moore¹³ noted precordial pain of a few days' duration in a secondary case which subsided under specific therapy. But opinions differ widely. Turner and White¹⁰ report a study of 50 cases of primary and secondary syphilis, excluding all cases over 40 years to eliminate coronary sclerosis. There were no cases of hypertension or recognized arteriosclerosis and, so far as possible, other infections were excluded. They found no definite clinical evidence of cardiovascular disease and conclude that "a critical study of the literature shows that clinical evidence of cardiovascular disease in early syphilis is rare."

Wile and Marshall,¹⁴ Friedman,⁷ Lucke and Rea,¹⁵ et al., have called attention to an apparent selective affinity of the spirochete for certain tissues and to the fact that, dependent upon individual and racial differences, certain tissues appear to bear the brunt of the attack. Musser and Bennett¹⁶ describe a vasotrophic and neurotrophic strain of spirochetes.

CONCOMITANCE OF CARDIOVASCULAR SYPHILIS AND NEUROSYPHILIS

It is with this subject that the present study is especially concerned. Here again opinions differ widely as to the frequency of this association.

The frequency of occurrence of neurosyphilis in cardiovascular syphilis is given as follows Lendon⁸—10 per cent in whites, Riven and Feigenbaum¹⁷—10 per cent, White¹⁸—16 to 20 per cent with 33·3 per cent on pathological evidence, Coombs¹⁹ quotes Hubert as reporting 25 per cent of 300 cases of cardiac syphilis as also having tabes Moore² states that while not all patients with cardiovascular syphilis have tabes, practically all tabetic patients have syphilitic aortitis On this point—namely, the occurrence of cardiovascular syphilis in neurosyphilis—there is similar divergence of opinion from Friedman's⁷ statement of 10 to 20 per cent to Kurtz and Eyster's²⁰ report of the finding by fluoroscopic means of aortitis in 95·7 per cent and of aneurysms in 21·8 per cent of their cases of neurosyphilis In view of this wide difference, we concluded that an especial study of this relationship might explain this discrepancy and furnish an acceptable percentage of concomitance

PURPOSE OF THE PRESENT STUDY

- 1 To determine the frequency of cardiovascular syphilis in neurosyphilis
- 2 To determine the frequency of diagnosable cardiovascular syphilis in neurosyphilis
- 3 To determine the value of the electrocardiogram in the diagnosis of cardiovascular syphilis

MATERIAL

The data in this report are based upon a study of 215 cases of neurosyphilis in the Colorado Psychopathic Hospital at Denver between October 1929, and September 1933 These cases are divided into paresis, tabo-paresis, tabes dorsalis, and meningo-vascular syphilis as follows

| | | |
|-----------------------------|------------|---------------|
| A Paretics | 145 | 67·4 per cent |
| B Tabo-paretics | 15 | 6·8 |
| C Tabes | 18 | 8·3 |
| D Meningo-vascular syphilis | 37 | 17·5 |
| Total | <u>215</u> | |

Each case was further grouped as follows

- | | |
|-----------|---|
| Group I | Physical and roentgen-ray findings normal |
| Group II | Physical findings abnormal, roentgen-ray normal |
| Group III | Physical findings normal, roentgen-ray abnormal |
| Group IV | Physical findings abnormal, roentgen-ray abnormal |

Each case had a careful historical investigation, was examined by one or two physicians, and in all questionable cases by a consulting internist All patients showing any historical or clinical evidence of rheumatic heart disease (10 cases) were excluded, as were also five cases insufficiently

studied for inclusion in this series As a control group we studied in a similar complete manner 100 consecutive non-syphilitic cases in the same hospital

TABLE I

To show the age distribution of the entire group of 215 cases with reference to Groups A (Paretic), B (Tabo Paretic), C (Tabetic), D (Meningo-Vascular), and Classes I (Normal Physical), II (Abnormal Physical), III (Normal Physical), (Normal X-Ray) (Normal X-Ray) (Abnormal X-Ray) IV (Abnormal Physical) (Abnormal X-Ray)

| Groups | Totals | Ages 21-30 | | | | Ages 31-40 | | | | Ages 41-50 | | | | Ages 51-60 | | | | Ages 61-70 | | | |

| Percentage of 215 cases | 17.5 | 1.8 | | | | 5.0 | | | 0.5 | 1.8 | 0.9 | 2.3 | 0.5 | 1.3 | | 0.9 | 1.3 | 0.5 | | | |

Table 1 shows

1 That a very large proportion (62.8 per cent) of these cases occur in the fourth and fifth decades and 6.3 per cent in the third decade before arteriosclerotic changes are of significance The average age was 45 years

2 That 33.9 per cent of the entire series occur among paretics between 31 and 50 (20.9 per cent 31-40) and that the cases included in this percentage are not diagnosed by physical or roentgen-ray methods

3 That 31.4 per cent of the syphilitic group occur after 50, 6.4 per cent of our controls fall in the fourth and fifth decades (31-50), 1.6 per cent before 30, and 2.0 per cent after 50

Of the 215 cases of neurosyphilis 73, or 33.9 per cent, showed some form of cardiovascular pathology independent of the electrocardiogram Of these 73 cases 57 were complicated and uncomplicated aortitis Of the remaining 16 cases three showed myocarditis without aortitis, five hypertensive heart disease, and eight were unclassified

Table 6, in which appears a summary of all autopsy reports on this complete series, presents a check on the accuracy of the clinical diagnoses Of the 14 cases coming to autopsy, in two only were the clinical findings not verified at autopsy, in these we failed to recognize an aortitis when present While this is a small number of autopsies it represents reports on 4.2 per cent of those who have died, and furnishes a fairly good check on the accuracy of the diagnosis of aortitis in this institution

TABLE II

Relationship of Aortitis and Aortitis with Complications to Electrocardiographic Changes

| Groups | Aortitis | Aortic Insufficiency with Aortitis | Aortitis with Hypertensive Heart Disease | Aortitis with Myocarditis | Aortitis with Aneurysm |
|--------|--|---|--|---|---------------------------|
| I | | | | | - |
| II | | | | | |
| III | Normal 8 Abnormal 9 Questionable 4 No EKG 7 Total 28 | | Abnormal 1 | | Abnormal 2 |
| IV | Normal 3 Abnormal 4 Questionable 2 Total 9 | Abnormal 4 Questionable 1 Total 5 | Normal 3 Abnormal 3 No EKG 2 Total 8 | Normal 1 Abnormal 1 No EKG 1 Total 3 | Questionable 1 |

Analysis of table 2 shows that no cases of aortitis were diagnosed save in the presence of roentgen-ray abnormalities, although 26 of 57 cases of aortitis showed in addition to roentgen-ray changes definite physical signs of heart disease. Table 2 further shows the frequency of electrocardiographic changes in each of these clinical groups. Uncomplicated aortitis shows electrocardiographic abnormalities less frequently than complicated aortitis, and when present these presumably indicate an associated coronary involvement sufficient to modify the nutrition of the heart muscle, although usually not sufficient to produce characteristic coronary changes.

Electrocardiograms were obtained on 47 of the 57 aortitis cases, and in 24, or 51 per cent, the curves were definitely abnormal, while in eight, or 17 per cent, the curves were considered questionable, making a total of 68 per cent of either abnormal or questionable electrocardiograms in this group of aortitis patients.

ELECTROCARDIOGRAPHIC STUDIES

The criteria employed were those approved by the American Heart Association²¹

In an earlier publication one of us (C T B)²² has shown that low voltage of R (not more than 5 to 8 mm) occurring in Leads I or II "is of sufficient value to be considered in connection with the prognosis of any cardiac case." This standard is less rigid than that of Sprague and White²³ and that of the Committee referred to in the foregoing paragraph. To avoid any criticism as to standards it has seemed preferable in the present study to adhere throughout to the accepted criteria.

The eight questionable abnormal curves (table 2) showed slurred R-waves in two cases, high R-wave in two, low R-wave in one, a questionable coronary S-T in one, slight left axis deviation in two, R-wave inverted in one, and T-wave inverted in one, but while all of these represented deviations from the normal, a conservative reading justified the interpretation of questionably abnormal rather than clearly abnormal electrocardiograms. Approximately 11 per cent, or every ninth, of all our curves fell in this class. In all cases of left axis deviation the habitus of the individual was considered and only those were regarded as abnormal in which the sthenic habitus could be excluded.

An electrocardiogram was obtained in 114 of the 145 paretics studied. Table 3 shows the distribution with reference to physical, roentgen-ray and

TABLE III

To Show the Distribution of 114 Paretic, 20 Tabetic and Tabo Paretic, and 30 Meningo Vascular Cases with Reference to Physical, X-Ray, and Electrocardiographic Changes

| Electrocardiograms | Physical and X-Ray Examination | | | | | | | |
|--|--|-------------|---|-------------|--|-------------|---|-------------|
| | Group I Normal Physical Normal X-Ray | | Group II Abnormal Physical Normal X-Ray | | Group III Normal Physical Abnormal X-Ray | | Group IV Abnormal Physical Abnormal X-Ray | |
| | Number of Cases | Per cent | Number of Cases | Per cent | Number of Cases | Per cent | Number of Cases | Per cent |
| <i>Paretics (114 cases)</i> | 72 | 100 0 | 7 | 100 0 | 19 | 100 0 | 16 | 100 0 |
| Normal | 48 | 66 7 | 2 | 28 5 | 8 | 42 1 | 4 | 25 0 |
| Abnormal | 17 | 23 6 | 4 | 57 1 | 8 | 42 1 | 9 | 56 3 |
| Questionable | 7 | 9 7 | 1 | 14 3 | 3 | 15 8 | 3 | 18 7 |
| Abnormal and Questionable | 24 | 33 3 | 5 | 71 4 | 11 | 57 9 | 12 | 75 0 |
| <i>Tabo Paretics and Tabetics (20 cases)</i> | 13 | 100 0 | 2 | 100 0 | 2 | 100 0 | 3 | 100 0 |
| Normal | 10 | 77 0 | 1 | 50 0 | 1 | 50 0 | 0 | 0 0 |
| Abnormal | 2 | 15 4 | 1 | 50 0 | 1 | 50 0 | 3 | 100 0 |
| Questionable | 1 | 7 6 | 0 | 0 0 | 0 | 0 0 | 0 | 0 0 |
| Abnormal and Questionable | 3 | 23 0 | 1 | 50 0 | 1 | 50 0 | 3 | 100 0 |
| <i>Meningo Vascular (30 cases)</i> | 18 | 100 0 | 1 | 100 0 | 6 | 100 0 | 5 | 100 0 |
| Normal | 10 | 55 6 | 1 | 100 0 | 0 | 0 0 | 2 | 40 0 |
| Abnormal | 6 | 33 3 | 0 | 0 0 | 5 | 83 3 | 2 | 40 0 |
| Questionable | 2 | 11 1 | 0 | 0 0 | 1 | 16 7 | 1 | 20 0 |
| Abnormal and Questionable | 8 | 44 4 | 0 | 0 0 | 6 | 100 0 | 3 | 60 0 |

electrocardiographic changes in this group of 114 paretics and also shows as follows

1 33 3 per cent abnormal or questionable electrocardiograms in paretics Group I

2 71 4 per cent abnormal or questionable electrocardiograms in paretics Group II

3 57.9 per cent abnormal or questionable electrocardiograms in paretics Group III

4 75 per cent abnormal or questionable electrocardiograms in paretics Group IV

We find that one-third of paretics without physical or roentgen-ray changes show an abnormal electrocardiogram, and this is abnormal much more frequently in the presence of physical, roentgen-ray or combined physical and roentgen-ray abnormalities. Abnormal physical signs appear to be more frequently associated with electrocardiographic changes than are roentgen-ray changes alone.

Twenty tabetics and tabo-paretics were similarly studied and in table 3 we show that in Group I, 23 per cent of the electrocardiograms are abnormal and, as in the paretic Groups II, III and IV, show a marked increase in the incidence of electrocardiographic abnormalities. Thirty meningo-vascular cases show 44.4 per cent electrocardiographic abnormalities in Group I. As in the paretics, tabetics and tabo-paretics an increase in electrocardiographic abnormalities is noted in the other groups, especially Group III, which shows practically 100 per cent abnormalities.

Especial interest attaches to the question as to what per cent of these cases, which were clinically normal from the cardiovascular standpoint, will show electrocardiographic abnormalities.

Table 4 shows 103 cases of central nervous system syphilis which on physical and roentgen-ray examination we considered normal from the cardiac standpoint.

TABLE IV

To Show the Incidence of Electrocardiographic Changes in Group I (Normal Physical and Normal X-Ray) in 72 Paretic, 13 Tabo-Paretic and Tabetic, and 18 Meningo-Vascular Cases

| Electrocardiogram | Group I Paretic Normal Physical Normal X-Ray | Group I Tabetic and Tabo-Paretic Normal Physical Normal X-Ray | Group I Meningo-Vascular Normal Physical Normal X-Ray |
|--------------------------------------|---|---|--|
| <i>Normal EKG</i> | | | |
| Number of cases | 48 | 10 | 10 |
| Per cent of cases | 66.7% | 76.9% | 55.5% |
| <i>Abnormal EKG</i> | | | |
| Number of cases | 17 | 2 | 6 |
| Per cent of cases | 23.6% | 15.4% | 33.3% |
| <i>Questionable EKG</i> | | | |
| Number of cases | 7 | 1 | 2 |
| Per cent of cases | 9.7% | 7.6% | 11.1% |
| <i>Abnormal and Questionable EKG</i> | | | |
| Number of cases | 24 | 3 | 8 |
| Per cent of cases | 33.3% | 23% | 44.4% |
| Totals | 72 | 13 | 18 |

Of the 72 paretics, 33.3 per cent showed abnormal or questionable electrocardiograms

Of the 13 tabo-paretics and tabetics, 23 per cent showed abnormal or questionable electrocardiograms

Of the 18 meningo-vascular cases, 44.4 per cent showed abnormal or questionable electrocardiograms

While the number of meningo-vascular cases is small as compared to that of the paretics the high percentage of electrocardiographic abnormalities is striking and suggests that the selective affinity of the spirochete for certain tissues discussed earlier in this paper may well explain this increased frequency of electrocardiographic abnormalities as compared with the paretic group

SUMMARY OF ELECTROCARDIOGRAPHIC FINDINGS

Of 215 syphilitic cases, electrocardiograms were obtained in 164 and were abnormal or questionable in 47 per cent. Of 100 hospital control cases electrocardiograms were obtained on 100, and were abnormal in 33 per cent. Many of these changes were slight—especially in the control group—and included axis deviation and departures from the normal which could hardly be considered significant. Furthermore, in the syphilitic group multiple changes and changes involving all leads were much more frequent.

Our hospital control series consists of a group of 100 consecutive Psychopathic Hospital patients (average age 40 years) in whom there was no evidence of syphilis. Seven of these showed physical evidence of heart disease—a much higher incidence than in the general population. Therefore, we considered this an unsatisfactory control and planned a further control series. There were, however, no roentgen-ray changes in this control group. The high incidence of electrocardiographic abnormalities in these hospital patients is probably accounted for by the fact that they had undergone cardiac changes which would not be encountered in a control group of normal individuals.

Since this control series of hospital patients appeared in some respects to be unsatisfactory, we studied a second control series of individuals who were theoretically normal, although not comparable as to age.

One hundred medical students of an average age of 26 years (the extreme ages being 21 and 42) were submitted to physical, roentgen-ray and electrocardiographic examinations. Of these, 94 furnished normal electrocardiograms employing the same standards as have been mentioned in the preceding text. Eighty-five of these showing normal electrocardiograms were found normal on physical and roentgen-ray investigation, five showed physical abnormalities but normal roentgen-rays, and four presented physical or roentgen-ray abnormalities, but none of these was considered indicative of heart disease. In two fibroid phthisis was the

cause of cardiac displacement Of the group of five showing abnormal physical signs a definite cardiac diagnosis was made in three cases, in one mitral stenosis and insufficiency, and in two mitral insufficiency, but in the remaining two faint systolic murmurs at the apex, not transmitted, were the sole abnormalities and probably were of functional origin Of this group of 100 students there was therefore an incidence of clinical cardiac pathology of 3 per cent—a percentage in line with accepted standards

In the interpretation of the teleroentgenograms the small, the "asthenic" or the "drop" heart, the transverse heart and very slight right displacement, in the absence of other roentgen-ray or clinical evidence, were classed as normal

Of the 100 controls in this series only six showed abnormal electrocardiograms, but all of these appeared normal on physical and roentgen-ray examination In this connection it is interesting to note that the three individuals in whom a definite cardiac diagnosis could be made showed normal curves

In six of the 100 controls the electrocardiograms were considered abnormal In two there was abnormal right axis deviation without other change in the QRS complex, in one there was abnormal left axis deviation, in one abnormal left axis deviation with other changes in the QRS complex, in one T_{1+2} were low and T_3 inverted, and in one there was low voltage of the R-wave in all leads

The abnormalities noted in the six controls showing abnormal electrocardiograms are summarized as follows

| | |
|---|---------|
| Abnormal right axis deviation without other QRS changes | 2 |
| Abnormal left axis deviation without other QRS changes | 1 |
| Abnormal left axis deviation with other QRS changes | 1 |
| Low voltage of R_{1+2+3} | 1 |
| Low voltage of T_{1+2} with T_3 inverted | 1 |
| Total | <hr/> 6 |

Table 5 furnishes a comparison of the significant electrocardiographic findings in our patients falling in Group I and those of our two control series Ninety-three of the hospital control series would likewise fall in Group I since only seven of the 100 hospital control patients showed physical evidence of heart disease, and none of them roentgen-ray abnormalities Likewise 97 of our student control may be considered as comparable to Group I, since in all others showing abnormalities the physical or roentgen-ray findings were not considered to indicate heart disease We show that *R-S-T wave abnormalities, usually associated with coronary and myocardial changes, occur much more frequently in the syphilitic group, and that the coronary S-T curve occurs exclusively in this group* (9 cases) Because of multiple changes found in a single electrocardiogram, percentage comparisons as to the foregoing changes are confusing and therefore omitted Axis deviation was of no value in diagnosis

TABLE V

Electrocardiographic Findings in Group I (Physical and X-Ray Findings Normal) on 103 Cases of Central Nervous System Syphilis as Compared with Control Groups

| Electrocardiographic Findings | Central Nervous System Syphilis | | Controls | |
|---------------------------------|---------------------------------|----|-------------------|---------------------|
| | | | 93 Hospital Cases | 97 Medical Students |
| R-wave low | | 8 | 5 | 2 |
| R-wave slurred in Leads I or II | | 12 | 8 | 2 |
| T-wave changes significant * | High | 7 | 4 | 0 |
| | Low | 11 | | |
| | Inverted | 4 | | |
| Coronary changes ** | Unquestionable | 6 | 0 | 0 |
| | Probable | 3 | | |

* High T-wave or T-wave inverted

** Includes Pardee curve

We find that the greatest percentage of electrocardiographic changes occurs a decade earlier (fourth decade) in our syphilitic group than in the hospital control group of comparable age, suggesting an earlier cardiac involvement in syphilis

Leary and Wearn²⁴ have stressed the infrequency of coronary as compared to cerebral involvement in syphilis and suggest that where there is coronary closure, an adequate myocardial circulation may be maintained by means of the Thebesian veins, first demonstrated as far back as 1706 Pratt²⁵ likewise in 1898 showed the possibility of a blood supply from the ventricles directly to the heart muscle. We show a significant incidence of coronary involvement. The fact that many of these patients failed to present symptomatic evidence may be explained on the foregoing basis.

The percentage of abnormal electrocardiograms is higher in the syphilitic group (47 per cent) than in the hospital control group (33 per cent), and because of this high percentage in the control group we have presented a student control group showing only 6 per cent of abnormal electrocardiograms. Yet there was no significant change noted in the syphilitic group which was not found in the hospital control group with the sole exception of the coronary S-T change found in nine cases. It thus appears that while electrocardiographic changes occur in greater frequency in syphilis than in a control group of comparable non-syphilitic individuals, there is nothing sufficiently characteristic in the electrocardiograms of these patients to be of more than confirmative evidence when considered in association with the clinical findings in the case, but there will often occur evidence of coronary and myocardial change in the heart of the syphilitic patient not demonstrable by other than graphic means. The electrocardiogram is therefore of considerable value in the diagnosis and subsequent management of the patient.

PATHOLOGIC STUDIES

Thirty-three patients died and autopsies were obtained on 14 or 42 per cent

Table 6 shows that in Case 4726 a definite syphilitic aortitis was not diagnosed. In Case 5016 the evidence was not so clear, but the pathologist after considerable study classified this as syphilitic aortitis, likewise not

TABLE VI

Relation Between Physical Changes and Aortic Changes as Disclosed by Microscopic Findings

| Hospital Number | Age | Duration of Symptoms (Chancre) | Physical Findings | Microscopic Condition of the Aorta |
|-----------------|-----|--------------------------------|---|--|
| 3360 | 48 | 28 years | Negative | No evidence of syphilis |
| 3921 | 53 | ? | Negative | No evidence of syphilis |
| 5067 | 27 | 10 years | Negative | No evidence of syphilis |
| 3316 | 48 | 10 years | Negative | No evidence of syphilis |
| 3654 | 40 | 12 years | Negative | No evidence of syphilis |
| 4113 | 26 | 4 years | Negative | No evidence of syphilis |
| 4699 | 53 | ? | Negative | No evidence of syphilis |
| 3599 | 49 | 30 years | Negative | No evidence of syphilis |
| | | | | Some lymphocytic infiltration in adventitia. No definite evidence of syphilis, but suspicious |
| 5016 | 65 | 20 years | Negative | Marked lymphocytic infiltration of adventitia. Patches of necrosis of media. Fibrosis of intima. Syphilitic aortitis |
| 4726 | 39 | ? | Negative | Syphilitic aortitis |
| 5146 | 58 | 31 years | Aortitis, hypertrophy, hypertensive heart disease | Syphilis of aorta and aortic valves |
| 4184 | 61 | ? | Aortitis with aortic insufficiency | Syphilis of the aorta |
| 5496 | 48 | 25 years | Aortitis | Suggestive changes indicative of syphilitic aortitis |
| 4376 | 55 | ? | Aortitis, hypertension, myocardial insufficiency | Syphilitic aortitis |

diagnosed ante mortem. In the remaining 12 cases the antemortem diagnosis was confirmed.

CHANGE IN THE ELECTROCARDIOGRAM AFTER MALARIAL TREATMENT

The literature presents occasional cases of sudden death in the course of malarial treatment of paresis—in the absence of clinical evidence of heart involvement. Bach and Worster-Drought,²⁶ discussing this, state that at autopsy invariably aortitis or myocarditis was found. We find no reports in the literature of electrocardiographic studies of these cases, but Mikawa²⁷ and his associates studied the effect upon the electrocardiogram in patients inoculated with malaria in the treatment of gonorrhea. They showed some amplitude changes, especially in the S-wave in the course of the fever, and a transient conduction disturbance, but failed to state the duration of this disturbance. Thirty-nine of our malarial treatment cases had electrocardiograms before and after treatment, there was no change

in 54 per cent, a slight change in 28 per cent and a definite change in 18 per cent, but the duration and meaning of this change has not been determined

This is a very small group of cases but, excepting Mikawa's studies which were on six patients only, we appear to present the only existing information on the subject

Slight shift of the axis to the right after treatment was observed five times, was unchanged twice and disappeared in one instance. Thus in eight of 18 cases there was slight axis shifting, usually to the left. T-wave changes, especially in Leads II and III, either a tendency to flattening of the wave or inversion of the wave, were the only other changes at all frequent. Some change in the T-wave occurred in seven cases. Certainly this group is too small to justify any conclusions drawn from the foregoing observations

We have not attempted in this paper any consideration of the effects of treatment upon established cardiovascular syphilis, but will record the observation that two cases, 8 and 11, showed a significant diminution in size of the aorta following malarial treatment

THE EFFECT OF TREATMENT UPON THE INCUBATION PERIOD OF NEUROSYPHILIS

Considerable controversy is current as to the merits of early treatment of syphilis, especially the use of arsphenamine. Wilmanns and Steiner²⁹ hold that this treatment predisposes the syphilitic patient to the development of parenchymatous neurosyphilis, while Smith and Frankl³⁰ do not concur in this viewpoint. German and French workers³¹ have shown that the treatment of early syphilis has shortened the period of incubation in parenchymatous neurosyphilis whether treated with mercury or arsphenamine. Moore and Hopkins³² report that adequate and proper treatment of late nonsymptomatic neurosyphilis will prevent the development of clinical neurosyphilis. Hopkins²⁸ has pointed out that "inadequate treatment of early or late syphilis shortens the incubation period not only of tabes and dementia paralytica, but also of late meningo-vascular neurosyphilis." In this paper the term incubation period is used to denote the period elapsing between the primary lesion and the appearance of symptoms of neurosyphilis.

It is interesting to note that in this group of 215 proved cases of central nervous system syphilis only 72, or 30 per cent, gave a history of a chancre, of these 72, only 22 gave a history of some form of therapy.

In each case which gave a definite history of treatment we have attempted to gain a full history of the nature of such treatment. While in some few cases this was unsatisfactory, we feel that the majority of cases have related a complete history of their treatment. In none of these was the luetic condition adequately treated according to present day accepted

standards In keeping with this, we submit the following statement taken from one of the cases which is fairly typical

Chancre contracted in 1907, while in the Navy Treated in Naval Hospital in Brooklyn, given calomel and potash for a period of two months No further treatment until 1922 took four courses of four treatments each In 1928 took four treatments of neosalvarsan Some iodine was also taken at that time In January and March 1930, took six treatments of neosalvarsan, also had two Swift-Ellis treatments

With the past and present emphasis placed upon the need of early and adequate treatment of syphilis it is surprising that in our series only 10.2 per cent of the cases were treated, whereas Hopkins²⁸ reports 43 per cent

In Table 7 we present evidence to show that inadequate treatment of

TABLE VII

The Influence of Inadequate Treatment Upon Incubation Period of 72 Cases of Neurosyphilis

| | Paretics | | Tabo-Paretics | | Tabetics | | Meningo-Vasculars | |
|-----------------------------|----------|----------------------|---------------|----------------------|----------|----------------------|-------------------|----------------------|
| | Cases | Period of Incubation | Cases | Period of Incubation | Cases | Period of Incubation | Cases | Period of Incubation |
| Cases not treated | 29 | 16.97 years | 4 | 22.10 years | 6 | 20.30 years | 11 | 14.30 years |
| Cases inadequately treated | 14 | 14.20 years | 0 | | 4 | 10.50 years | 4 | 7.90 years |
| Total number of cases | 43 | | 4 | | 10 | | 15 | |
| Incubation period shortened | | 2.77 years | | | | 9.8 years | | 6.4 years |

early and late syphilis shortens the period of incubation of paresis, tabes dorsalis, and meningo-vascular syphilis In paresis this amounted to 2.77 years on the basis of 43 cases, in tabes dorsalis 9.8 years on the basis of 10 cases, and in meningo-vascular syphilis 6.4 years on the basis of 15 cases

THE EFFECT OF TREATMENT UPON THE TIME OF APPEARANCE OF SIGNS OF HEART INVOLVEMENT

We have also studied these cases from the standpoint of their cardiac changes The results are presented in table 8 Of the 50 untreated cases, 22 per cent were found to be abnormal on physical and roentgen-ray examination, while of the 22 inadequately treated cases 41 per cent were abnormal—that is, cardiac changes demonstrable by physical and roentgen-ray means were found approximately twice as often in the inadequately treated cases as in the untreated cases On the basis of 57 electrocardiograms performed on the 72 patients giving a history of syphilis, abnormal curves occurred more frequently in the inadequately treated group than in the non-treated group, although not to the same extent as above

Emphasis should be placed upon the potential danger of inadequate treatment in early and late syphilis as such treatment apparently interferes

TABLE VIII

The Contrast of Inadequate Treatment and No Treatment as Shown by Physical, X-Ray, and Electrocardiographic Changes

| Groups | Non-Treated Cases | | Inadequately Treated Cases | |
|-----------------------------|-------------------|----------|----------------------------|----------|
| | Number | Per Cent | Number | Per Cent |
| I Normal Physical and X-Ray | 39 | 78 | 13 | 59 |
| II, III, IV—Either Abnormal | 11 | 22 | 9 | 41 |
| Physical or X-Ray or Both | 50 | 100 | 22 | 100 |
| Totals | | | | |
| Normal Electrocardiogram | 24 | 60 | 8 | 47 |
| Abnormal Electrocardiogram | 16 | 40 | 9 | 53 |
| Totals | 40 | 100 | 17 | 100 |

with the resistance-building mechanism of the body and predisposes the patient not only to the development of neurosyphilis but of cardiac syphilis as well. At the present time we do not have sufficient data to report the incidence of neurosyphilis in adequately treated early cases of syphilis. Incomplete data indicate that the incidence is very low.

SUMMARY AND CONCLUSIONS

We have intensively studied a group of 215 cases of neurosyphilis in order to determine the frequency and type of cardiovascular involvement.

1 We find that 73, or 33.9 per cent, show some form of cardiovascular pathology, independent of the electrocardiogram.

2 Our findings are in agreement with others as to the importance of aortitis in syphilis, it furnishing the most frequent type of cardiovascular pathology in syphilis.

3 In association with syphilitic aortitis we find electrocardiographic abnormalities in 68 per cent of our cases.

4 33.3 per cent of our paretics, 23 per cent of our tabo-paretics and tabetics, and 44.4 per cent of our meningo-vascular cases, without physical or roentgen-ray abnormalities of the heart, showed abnormal electrocardiograms, and the electrocardiogram was abnormal in a much higher proportion in the presence of physical, roentgen-ray or combined physical and roentgen-ray abnormalities. Abnormal physical signs appear to be more frequently associated with electrocardiographic changes than are roentgen-ray changes alone.

5 We find a significant increase in electrocardiographic abnormalities in neurosyphilis, but no change which can be considered as characteristic of cardiovascular syphilis, although we are impressed with the incidence of coronary changes in our series.

6 The incidence of electrocardiographic abnormalities not associated with physical or roentgen-ray changes noted in this series of neurosyphilitics

justifies the routine use of the electrocardiogram in these cases as a means of an earlier recognition of cardiovascular involvement

7 The incubation period of neurosyphilis is shortened in paretics, tabetics, and meningo-vascular cases who have received early or late, but inadequate treatment

8 Cardiac lesions seem to be found more frequently in those cases inadequately treated. This is demonstrable by either physical, roentgen-ray, or electrocardiographic changes

9 There is definite need for more adequate therapeutic procedures in early and late syphilis to decrease the incidence of neurosyphilis

ABDOMINAL PAIN· ITS SIGNIFICANCE AND DIAGNOSTIC VALUE^{*}

By THOMAS R. BROWN, M D , F A C P , *Baltimore, Maryland*

THE diagnosis of intra-abdominal pathology is extremely difficult. We have no method for exact diagnosis such as the electrocardiogram for the cardiac lesion, the blood in primary anemias, the urine and functional studies in the nephritides and the sputum in pulmonary tuberculosis. We are helped a little in making such diagnoses by the study of gastric and duodenal contents, more by study of the stool, much more by fluoroscopy and radiography of the digestive tract. The physical examination of the abdomen is of course essential, often, however, in its interpretation puzzling and indefinite. Therefore, in many cases, in making a definite or potential diagnosis, we must depend upon the analysis and interpretation of the symptoms, the history of the case, its beginning, its evolution, upon our proper interpretation of these our final diagnosis often depends.

Few of these symptoms are diagnostic in themselves, for example, constipation may simply represent faulty habits of eating and living and be purely functional, but it may be the first sign of a colonic neoplasm or of some extra-gastrointestinal disease as, for example, unsuspected hypothyroidism, while an intractable diarrhea, usually of gastrogenous or enterogenous origin, may be the first and only symptom of the opposite condition—hyperthyroidism. Nausea, distress and vomiting may be of gastric or intestinal origin, but it may also represent the main symptoms of cardiac or renal disease, of gall-bladder pathology, or may be purely psychogenic—the mirror of a disturbed mind or the expression of maladjustment to the environment. But the symptom which most frequently brings the patient to the doctor, the symptom whose correct interpretation is most important in helping us to a correct diagnosis, is pain.

The cause of superficial pain is simple and easy to understand—specific pain nerves with exquisite localizing powers furnish a protective mechanism to external trauma and are essential to the preservation of the individual and the evolution of the race. The cause of visceral pain is not simple and is not easily explained. There are no such specific pain nerves as are met with in the skin and no need for them as the viscera are protected against external trauma by the bony and muscular cage which encloses them. The normal physiology of digestion proceeds automatically and autonomically. Health is spelt by a proper balance between two opposing sets of impulses—one stimulating, one inhibiting, pain or discomfort probably represents lack of balance in this mechanism, usually secondary to organic pathology in the viscera themselves. And thus, what we interpret as pain, in reality probably represents change in intra-gastric or intra-intestinal pressure, increased tonus, or hyperactive peristalsis.

^{*} Read at the Chicago meeting of the American College of Physicians, April 20, 1934

Most investigators feel that there are few, if any, true pain fibers in the nerves supplying the abdominal organs. We know, for instance, that the viscera can be crushed or burnt or pressed upon with great force without any pain, though Langley and Gaskell believe that there are a few medullated sensory fibers in the splanchnics. These must be very few, if any, because of the obvious lack of sensation of the viscera in the ordinary sense and the extreme paucity of the afferent fibers in the nerves supplying the abdominal organs. We know that the visceral peritoneum is devoid of pain fibers. Capps believes that true sensory fibers may exist in the parietal peritoneum which may give rise to pain and to some extent localize it, but most physiologists think that in the parietal, as in the visceral, peritoneum there are no true pain fibers and that discomfort or pain produced by pressure is brought about by sensations arising from the rich nerve supply of the loose connective tissue external to the parietal peritoneum.

Certainly the weight of evidence is in favor of the view that there is almost complete absence of true pain receptors in the visceral walls. Many physiologists believe that hypertonus, increased pressure, and overactive peristalsis are the causes of so-called abdominal pain, that impulses may arise in afferent nerve endings of the viscera as a result of stretching or compression, that this pain is not localized but is usually referred to certain areas in the surface of the body and may be associated with superficial or even somewhat deeper sensitiveness of the cutaneous and muscular covering. But this explanation, while fairly satisfactory as regards the intestine, is not enough to explain the pain met with in certain other portions of the abdomen, notably the stomach. Here we must presuppose that the disease produces a very definite hypersensitiveness, possibly the development of irritable foci in certain regions of the spinal cord due to repeated abdominal impulses, possibly a local hypersensitiveness to any form of stimuli at the seat of the lesion itself as well.

Thus, in our analysis of the causes of abdominal pain, perhaps our best explanation is that abdominal impulses may result in referred pain—the viscerosensory reflexes—tenderness, that is cutaneous or muscular hyperalgesia, muscular contractions, that is muscle spasm or *défense musculaire*. Possibly certain sensations are due to a lowered threshold of pain or to hypersensitiveness in the lesion itself or in that area of the spinal cord connected with the lesion through its nerve supply.

Thus, abdominal pain is a very complex phenomenon and its interpretation may be made difficult by many confusing factors—the similarity of the nerve supply to many of the abdominal viscera as well as to certain contiguous organs such as the heart and lungs, the diversity of the paths through which painful sensations may leave the abdomen, the proximity of the visceral organs to each other—one's hand can almost cover gall-bladder, pylorus, duodenum and a segment of the transverse colon, while the thin diaphragm alone separates heart and lungs from liver, stomach and spleen. Perhaps an even more difficult factor in the interpretation of pain is the

enormous variation in the picture due to individual variation in response to stimuli

In analyzing and interpreting abdominal pain, we have to consider all of these factors—physiological imbalance, organic pathology, congenital or acquired, local or general hypersensitiveness, the overlapping and confusion of symptoms due to similar nerve supply and close proximity of organs, the whole modified to a tremendous degree by the emotional stability or instability of the patient

At the present time, this last factor has been given perhaps undue prominence. It is the fashion of the age to explain complaints on a purely psychogenic basis—emotional instability, lack of insight, maladjustment—and to advise a treatment based upon such a conception—reeducation, psychotherapy, the removal or minimization of psychic strain. This is a dangerous attitude of the mind as regards abdominal pain, for while minor discomfort may be exaggerated into exquisite pain by the neurotic, and all forms of pain may be simulated by the auto- or hetero-suggestion of the hysterical, these are usually recognized and properly interpreted by the competent physician. True abdominal pain usually means organic pathology and its underlying basis is usually structural change. It is a very dangerous thing to diagnose gastralgia or enteralgia and to ascribe to a psychasthenic state symptoms associated with true pain, especially if associated with rise of temperature, with local tenderness, with an increased leukocyte count. Too often such an interpretation will lead to deplorable delay and the appendix ruptures or an ulcer perforates while the patient is being treated on the assumption that the condition was purely functional.

In the interpretation of pain, its evolution, its localization, its radiation, its character, its constancy or its irregularity, its periodicity, there are certain general principles which one should never forget. First, that the pain is a summation of local pathology, organic or functional, and psychic response, thus a mild lesion in a psychasthenic individual may elicit much more complaint than a far more serious lesion in a stable person. Second, the size or extent of the lesion has absolutely no relation to the severity of the pain. A pin point erosion of the mucous membrane can produce as much pain as a deep callous ulcer, a small gall-stone usually gives much more pain than a large one, a gastric ulcer and even a duodenal ulcer may give no pain whatsoever, pain is absent in many cases of cancer of the stomach. It is the tragedy of cancer that pain is not an early symptom, often not even a late symptom, when it appears it usually represents the beginning of obstructive symptoms rather than anything integral to the growth of the cancer itself. Third, while the disappearance of pain usually means improvement, sometimes the reverse is true, as in a gangrenous appendix or gall-bladder.

There are certain pain patterns which we should never forget and which are almost diagnostic—pictures which give us our probable diagnosis from the history of the patient alone. Such is the pain of duodenal ulcer, with its relief by food, its periodicity, and its punctuality. Moynihan used to

say he could set his watch by the hunger pains of his patients, while as regards its periodicity, we all know that spring and fall are the times of election. Such also are the agonizing attacks of upper right quadrant colic with radiation to the right shoulder, so often met with in cholelithiasis and peculiarly likely to occur during the wee small hours of the night, the discomfort or cramp-like pain, beginning in the epigastrium and finally localizing in the lower right quadrant, of acute appendicitis, with its local tenderness, its muscle spasm, its constipation, nausea, fever and increased leukocyte count, the agonizing pain with circulatory collapse of acute pancreatitis and the somewhat similar picture of perforated ulcer with absence of early collapse, the periodic cramp-like pains due to intestinal obstruction, whatever its cause.

These are clear cut clinical pictures, where the location of the pain, the type of pain, the history of the pain, often without the associated clinical and laboratory findings, give us as a rule a definite diagnosis. But we must never forget that each one of these can be simulated by intra- or even extra-abdominal conditions in a certain small proportion of cases. Renal colic may absolutely simulate biliary colic, duodenal ulcer may occasionally give the picture of a gall-stone attack, while ulcer, gall-bladder disease or appendiceal disease may be simulated by a great number of other conditions which we will briefly touch upon later also. Every one of these conditions, which as a rule have such characteristic histories, may in certain instances have no local symptoms whatsoever, only symptoms referred elsewhere. For instance, in acute appendicitis, the pain may persist in the epigastric region, it may be only umbilical in location—this in about 5 per cent of the cases, it may simulate a gall-bladder attack or may produce pain only in the back or in the pelvic region or down the right leg.

In many other abdominal conditions, the pain picture or pattern may be suggestive, but not diagnostic. It is blurred, it is confused, as for instance in many cases of gastric ulcer, in a small number of cases of duodenal ulcer, in a larger number of cases of biliary tract disease, and in a considerable number of cases of intestinal obstruction due to neoplasm, postoperative adhesions, etc., where the symptoms are too often explained on a purely functional basis and operation often delayed far too long, especially in the malignant type of obstruction. The diagnosis of chronic appendicitis is unquestionably erroneous in the majority of cases, but it is justified in a small percentage of cases where the pathologic signs are in the lower right quadrant and the referred pain usually in the epigastrium though occasionally in the upper left quadrant.

We have not time, of course, to discuss in detail the many other intra-abdominal conditions where the pain is referred elsewhere in the abdomen or the innumerable cases of disease outside the abdominal cavity where one of the symptoms, sometimes the main symptom, occasionally the only symptom, is abdominal pain, but I do wish to mention certain of these that have

been singularly interesting to us in our very intensive study of abdominal pain over a long period of years

Let us first discuss briefly certain of the more puzzling examples of referred abdominal pain

True angina pectoris may present no symptoms above the diaphragm, only violent epigastric pain, without radiation. This unfortunately is only too often diagnosed as an acute indigestion and treated by purgatives and exercise, when morphia and rest may be the only means of saving life. Also a few cases of coronary thrombosis so exactly simulate gall-stone colic that gall-bladders, usually quite normal, have been removed on this false hypothesis. It is well to remember that in a very few instances the reverse of this picture is true—that is, unsuspected gall-bladder disease may present symptoms absolutely simulating attacks of stenocardia or coronary thrombosis. It is also well to remember that rare cases of carcinoma of the liver, and, somewhat more frequently, cases of hepatic cirrhosis may present, during their course, attacks absolutely simulating gall-stone colic, frequently incorrectly confirmed by Graham gall-bladder pictures. In reality the attacks represent no disease of the gall-bladder but acute infections or reinfections of the previously diseased liver.

Perhaps the best explanation of this correlation between cardiac and biliary phenomena is that given by Head: "When a painful stimulus is applied to a part of low sensibility in close central connection with a part of much higher sensibility, the pain is felt in the part of higher sensibility rather than in that of lower sensibility to which the stimulus is actually applied."

This also may be the explanation of the acute abdomen often simulating appendicitis which is met with occasionally in central pneumonia and diaphragmatic pleurisy.

While in many cases the peptic ulcer syndrome may require for its explanation a local hypersensitiveness to irritants, such as acid, or a general or central hypersensitiveness so often associated with emotional crises or psychic strain, nevertheless the bulk of the evidence favors the view that pyloric spasm, increased intragastric pressure, hypertonus and hyperperistalsis play the major rôle in its production. These motor disturbances can be produced so easily by referred impulses from disease elsewhere that it is not surprising that ulcer is often diagnosed in disease of many other organs. For example, in tabes dorsalis, where an Argyll Robertson pupil and absent knee jerks should have given us our clue, although unfortunately it is not infrequent that this clue is overlooked and even surgical treatment employed, in renal or urinary calculus where the urinary findings and a flat plate of the abdomen should have given us our diagnosis, in certain cases of gall-bladder disease where x-ray plates by the Graham method may help us, or in obstruction of the colon, whether benign or malignant, where there are no local symptoms, only those referred to the stomach. Of course in carcinoma of the colon or in obstruction due to other causes, this is not

the usual picture, and the pain, while not definitely localized, is usually in the lower abdomen, usually spasmodic, often with surprisingly long intervals between attacks, and generally misinterpreted for a long period of time. In reality everyone presenting such a syndrome should make us suspect early malignancy, especially in older people, and should set in motion that set of diagnostic procedures—palpation of the abdomen in a hot bath, fluoroscope of the colon by the barium enema, digital rectal examination, study of the stool for occult blood—that should either confirm or refute this suspicion.

A small epigastric hernia may produce pain absolutely similar to that of ulcer, and the same may be true of herpes zoster before the appearance of the eruption, although here, as a rule, the pain is much more likely to simulate acute appendicitis. Lower right quadrant pain simulating sub-acute or chronic appendicitis is met with in such a varied group of diseases elsewhere that it would be remarkable if incorrect diagnoses were not singularly likely to occur with this syndrome. Right-sided pyelitis, especially in young female children where the urine may be clear due to the plugging of the ureter on the infected side, true ureteral stricture (a rare condition), right salpingitis, ovarian cyst with twisted pedicle and tubal pregnancy, all present pictures suggestive of appendicitis, but usually differentiated by careful examination.

Perhaps equally interesting and certainly more puzzling is the picture suggesting an acutely diseased appendix met with in certain of the infectious diseases—notably measles before the appearance of the eruption, typhoid fever in its early stage, acute follicular tonsillitis, influenza, in a few instances even scarlet fever and undulant fever, the latter showing a peculiarly puzzling picture when it has mainly abdominal manifestations. Perhaps the best explanation in many of these cases is a marked localization of the infectious agent in the rich lymphoid tissue about the cecum. In this connection, we know that tuberculous or nontuberculous adenitis, localized in this area, may absolutely simulate appendicitis, while allergic phenomena, such as we meet with in angioneurotic edema or in Henoch's purpura, may present a similar lower right quadrant picture. Perhaps the most difficult of all to explain is the acute abdomen, usually simulating acute appendicitis, sometimes found in sickle cell anemia.

Space does not permit us to call attention to other rare causes of abdominal pain with which we have met. Each of these presents its own special problem, where a correct diagnosis is often singularly difficult, sometimes impossible, as for instance, chronic pancreatitis in the aged, a much neglected diagnosis, with epigastric pain, usually mild, the puzzling abdominal pain of arthritis of the spine, of aneurysm of the renal artery, of a psoas abscess or of a burrowing abscess secondary to a diverticulitis, of tuberculosis of the mesenteric or retroperitoneal glands, of an unsuspected localized osteomyelitis, mesenteric thrombosis, atypical ileus and chronic intussusception.

Each of these presents its individual problem, but in most cases this is capable of solution if the diagnostic procedure is thorough and the reasoning of the clinician logical.

In the solution of each of these abdominal problems, we must of course utilize every diagnostic procedure. We must take a careful and complete history, make a thorough physical examination, and utilize to the full the findings from the clinical and x-ray laboratories, but in almost every case, the pain picture is a valuable, often an invaluable, aid, while sometimes it is the only key that will unlock the closed door.

True clinical research is far more difficult than laboratory investigation, but if done scientifically and thoroughly by one who knows the art, as well as the science, of medicine, it is equally productive of results. In clinical research there is no more promising field than that of the interpretation of abdominal pain. It is a very difficult field—the picture often blurred, pain patterns overlapping because we are not analyzing pictures produced by true visceral pain fibers but are trying to interpret physiological dysfunction.

Sometimes the problem is insoluble, sometimes we have to say with Charles Mayo that it is not knowledge of anatomy and physiology which teaches us the significance of a certain pain, but experience with that same type of pain observed many times before, and what was found when the abdomen was opened. But in the majority of cases, the careful analysis of pain gives us valuable information and it may be the only solution to the diagnostic puzzle.

Are we trying to turn back the hands of the clock? I do not think so. We are simply repeating what Gowland Hopkins, the President of the Royal Society of London and the most distinguished research student in his own field, has said: "Experience at the bedside and the habit of close observation are essential for the making of a successful physician." We are simply stating that at the present writing the science of medicine alone, the results of clinical laboratory and x-ray studies, at least in the abdominal field, are not sufficient to lead to a correct diagnosis in most cases. It means we must not discard the art of medicine, and that the microscope, the test tube, the instruments of precision and the x-ray cannot as yet displace the eye, the ear, the finger, and the results of observation.

There is unquestionably too great a tendency at the present time to lean too heavily upon laboratory methods and too lightly upon pure clinical observation. If we recognize this imbalance and, while not neglecting the results of laboratory methods which are invaluable, attempt to recapture the marvelous clinical sense, the wonderful powers of observation, analysis and deduction of Bright and Addison and Sydenham, of Osler and Thayer, perhaps we may reach the point where we can say with Edmund von Neusser, the greatest clinician of his day, that "The history of the case should give us our correct diagnosis, the physical examination and laboratory tests should be merely confirmatory"—or even be able to confirm what Hilton said many decades ago—"Every pain has its distinct and pregnant significance if we will but carefully search for it."

FACTORS INFLUENCING OPERATIVE MORTALITY IN EXOPHTHALMIC GOITER *

By WILLARD O THOMPSON, M D , F A C P , SAMUEL G TAYLOR, III,
M D , and KARL A MEYER, M D , *Chicago, Illinois*

DURING the past 50 years much has been written about the surgical management of patients with toxic goiter. Just before the introduction of iodine 12 years ago, the operative mortality had shown a steady reduction with increasing experience until, in the best clinics, it varied from 1 to 4 per cent. Not only had the mortality as a whole shown a marked reduction, but the mortality record of every thyroid surgeon had shown a marked decrease as his experience increased. This drop in the mortality rate may be attributed to two factors: (1) increase in surgical skill and improvement in technic, (2) improvement in surgical judgment. Surgeons gradually had learned when to operate and when not to operate and what surgical procedures their patients would tolerate. They had learned not to operate when the disease was increasing in severity, that the presence of marked emotional instability meant that it was unwise to attempt surgery, that the production of a gain in weight by the administration of a high caloric diet was a favorable sign, that psychic traumata exaggerated the disease and hence should be avoided, and that all of the signs and symptoms of the disease diminished in intensity with rest. Most surgeons moreover had agreed that it was wise to perform the thyroidectomy in several stages in the more severe cases. It is of some interest that, as a result of the application of these principles, the mortality in the clinics of the best thyroid surgeons was lower before the days of iodine than the mortality in many clinics at the present time.

Following the demonstration of the marked beneficial effects of iodine in exophthalmic goiter by Plummer, there was a tendency in some quarters to ignore the lessons learned before its introduction and to place too much reliance on iodine. It was said that iodine abolished crises and the need for multiple stage operations. It became rather common to say that the treatment of exophthalmic goiter consisted in the administration of iodine for about 10 days, followed by the performance of a subtotal thyroidectomy. It gradually became apparent, however, that some patients were still dying of typical thyroid crises after operation and that some patients died even before operative procedures could be carried out, in spite of the administration of large doses of iodine and the institution of other therapeutic measures known to be of value. The past few years have, therefore, been characterized by a growing realization of the importance of factors found

* Read at the Chicago meeting of the American College of Physicians, April 20, 1934.
From the Department of Medicine, Rush Medical College, the Department of Surgery, Northwestern University Medical School, and the Cook County and Presbyterian Hospitals, Chicago.

to be of value before the days of iodine and by a more precise evaluation of the effect of iodine. The result is that we have come to regard iodine as a great help in preparing patients for operation, which must be used, not alone, but in conjunction with every other worthwhile therapeutic procedure.

The various factors of importance in the successful management of patients with toxic goiter may be discussed under the following headings:

- 1 The skill of the surgeon

- 2 Selection of the time and type of operation, with special reference to emotional instability, iodine, diet and rest

- 3 Treatment of complications

- 1 *The Skill of the Surgeon* In the successful outcome of all operative procedures surgical skill is a factor, and this is particularly true of thyroidectomies for exophthalmic goiter. In our experience, severe postoperative reactions and various complications of thyroidectomy have always been more common following surgical procedures carried out by inexperienced men than after those carried out by experienced men. We have repeatedly seen severe postoperative reactions follow hemithyroidectomies by inexperienced surgeons in patients that would probably have had mild reactions following subtotal thyroidectomies by experienced surgeons. We recall one young surgeon of little training who performed a thyroidectomy on a patient with exophthalmic goiter who had the disease in fairly mild form and in whom the emotional instability was not marked. From our observations, we predicted that the patient would have a mild postoperative reaction. Nevertheless, for 12 hours after operation, her pulse rate varied from 150 to 160 per minute and she was unduly sick. After this, and at about the time when the postoperative reaction usually becomes severe if it is going to, her pulse rate dropped markedly and she began to improve. Such a reaction we are inclined to attribute to direct trauma caused by unnecessary manipulation and prolongation of the operation through lack of surgical skill. We have pointed out elsewhere how the mortality rates of all prominent thyroid surgeons have steadily dropped with increasing experience. Men who become proficient in goiter surgery by doing large numbers of thyroidectomies over a long period will undoubtedly continue to have lower mortality rates than general surgeons who do a comparatively small number of thyroidectomies.

- 2 *Selection of the Time and Type of Operation* It has been rather generally taught that a thyroidectomy should be performed as soon as the basal metabolism shows a maximum reduction, namely about 10 days after the administration of iodine is started. In recent years, we have departed somewhat from this dictum and have made it a point not to have patients operated on until we thought they were ready, regardless of how long operation needs to be postponed. It has been our experience that maximum improvement does not occur as soon as the basal metabolism has shown a maximum reduction, but only some time later, when the patient has had an opportunity to derive the benefit of the lowered rate of metabolism. In

gauging the ability of patients to withstand operative procedures, we pay most attention to the intensity of emotional instability. The severity of the postoperative reaction more closely parallels this factor than any other, a fact pointed out by Plummet years ago. If, in spite of a well marked reduction in basal metabolism, the patient still thrashes about in bed and weeps at frequent intervals, it is probably unwise to attempt operation. We have reported elsewhere¹ data on two patients which illustrate the importance of considering emotional instability. One was a girl of 17 whose basal metabolism was plus 108 per cent on admission to the hospital. With rest and iodine the rate dropped to plus 32 per cent and her pulse from 125 to 71. However, marked emotional instability persisted up to the time of operation. Laughing would alternate with weeping for no apparent reason. The morning of the operation she wept violently. She was operated on after the conventional period of iodine administration and had lost no weight after admission to the hospital. At no time during operation did her pulse rate rise above 88, yet she died 48 hours after operation of an intense thyroid reaction. A large thymus was found at autopsy which may or may not have been related to her death according to the Graves' constitution theory of Warthin² and others. The other patient was a man of 50 whose basal metabolism dropped only slightly (from plus 46 per cent to plus 33 per cent) during the administration of iodine. Although he gained 2.5 kg. in weight before operation, the nervous manifestations of the disease persisted in a severe form and we were skeptical about his ability to withstand surgery. Nevertheless, he took the anesthetic well and it was decided to proceed with a subtotal thyroidectomy. He died about thirty hours after operation of a thyroid crisis complicated by bronchopneumonia.

This raises the question of the importance of the basal metabolism in gauging the operative risk. On the average, the lower the basal metabolism the better the operative risk, but there are many exceptions to this rule. We have seen only moderately severe postoperative reactions in patients in whom the basal metabolism showed no reduction during the administration of large doses of iodine and remained at a level of from 50 to 60 per cent above normal, while we have seen other patients die whose basal metabolism was only from 20 to 30 per cent above normal at the time of operation. The first group of patients were comparatively calm and the second group unstable emotionally and it is the intensity of this factor which seemed to be related to the severity of the postoperative reaction.

Contrary to the generally accepted teaching, the basal metabolism will rise very little in most cases during the administration of iodine if operation is delayed from two to three weeks beyond the time of maximum reduction. The danger of a rise in metabolism during several weeks of treatment with iodine with the patient at rest in bed in the hospital, has, in our opinion, been overemphasized. If the metabolism does rise slightly we ignore it in gauging the probable outcome of the operation. In a few cases, however, the metabolism rises rapidly after an initial drop in spite of the administration of iodine.

and sometimes to a higher level than before iodine was started. Associated with this rise in metabolism is an increase in the intensity of all the manifestations of the disease, including the nervous manifestations. Unfortunately this rise tends to occur in the patients who have the disease in the more severe form, that is in just those patients who need the benefit of rest most. This raises the problem of refractoriness to iodine and its management. We have reported elsewhere³ two patients who became partially and completely refractory respectively to about 6 milligrams of iodine daily in the form of Lugol's solution during its prolonged administration and who, after periods of omission of from 30 to 60 days, again showed a well marked response to it. It has never been conclusively established that patients become completely refractory to much larger doses of iodine after showing an initial response, although it is likely that this occurs, because a certain percentage of patients initially show no response to iodine. The main problem is whether the refractoriness is caused by the iodine itself or by a spontaneous variation in the intensity of the disease. If the iodine is responsible, then it should be omitted, whereas if the nature of the disease itself is responsible, then iodine should be continued, because many patients develop only partial and not complete refractoriness to it. While this point is yet unsettled, we do know that if the metabolism is rising rapidly it is usually safe to omit iodine and that after a period of omission, patients will usually respond to it again. The administration of enormous doses of iodine (100 minims of Lugol's solution daily) during the refractory period is of no more value than the administration of much smaller doses, although teaching to the contrary persists. It is probable that 5 minims of Lugol's solution daily always produces a maximum effect. We have observed previously⁴ about as much effect on metabolism in Boston during the administration of 1 minim of Lugol's solution daily as Lerman and Means⁵ did during the administration of 90 minims daily. We routinely use 10 minims of Lugol's solution three times a day. This dose is used partly as a matter of habit and partly to prevent criticism on that score by surgeons when they have poor results. The form in which iodine is administered is not of great importance. Sodium iodide and potassium iodide possess the advantage over Lugol's solution that they are more palatable. Iodine has no effect on the secretion of the thyroid after it leaves the gland. It is, however, given routinely after operation because in a varying percentage of cases (from 5 to 15 per cent), depending upon the surgeon, enough thyroid tissue is left at operation to cause the disease to persist in a subdued form. Since it is impossible to predict at the time of operation just which cases these will be, it is necessary to administer iodine post-operatively to all patients in order to control the thyrotoxicosis in the few instances in which it persists.

Muscle weakness is one of the characteristic findings in exophthalmic goiter and when marked, as judged by inability to climb up on a chair without assistance, usually means that operative procedures will not be well

tolerated. Marked muscle weakness and marked emotional instability usually but not always go hand in hand. It is a matter of experience that these two manifestations of the disease, like all the others, usually decrease in intensity with rest. Thyroidectomies for exophthalmic goiter are not emergency operations and if done as such, kill a large percentage of the patients operated upon. We therefore, make it a point to delay operation until we think the patient will stand it. During this period we keep the patient in the hospital and continue the administration of iodine. Rest is not complete and the usual ambulatory privileges are allowed, except in the presence of extreme muscle weakness or cardiac decompensation.

We have virtually abandoned the ligation of arteries as a surgical procedure in exophthalmic goiter because it appears to have no influence on the course of the disease. Its only indication would appear to be to test the ability of the patient to withstand more extensive operative procedures when there is any doubt about this, and it should be possible to gauge this in other ways. It has the disadvantage that it produces unsightly scars and often renders more difficult the technic of a subsequent thyroidectomy. It is the impression of most workers in the field that the severity of the postoperative reaction is directly related to the extent of the surgical procedures, that is, the amount of tissue removed. Lahey⁶ has said that hemithyroidectomies should be done in all patients in whom there is any doubt about the ability to withstand operation. Richter⁷ does not agree with this point of view and feels that his low mortality, even before the days of iodine, may be attributed to the fact that he left very little thyroid tissue to cause any reaction. If, in spite of the various precautions outlined, the patient still seems to be in poor condition for operation, roentgen-ray treatment may be used. This has to be carried out with caution in severe cases. Although it may not cure the disease, it usually reduces its intensity sufficiently to permit a thyroidectomy to be done with safety.

It is important to bear in mind that exophthalmic goiter is a disease in which body tissue is broken down at a rapid rate. It is reasonable to assume that the prevention of this breakdown is a desirable therapeutic procedure. It has been our experience that a well marked gain in weight before operation is a favorable prognostic sign. If combined with a well marked reduction in basal metabolism a satisfactory outcome of the operation is almost assured. In order to make the patients gain weight, it is usually necessary that the caloric intake exceed the basal caloric expenditure by at least 100 per cent. This means that most patients should receive from 4000 to 5000 calories daily. Such a diet invariably assures an adequate protein intake to offset the high nitrogen excretion often present in the disease.

By administering a meal consisting largely of carbohydrate four hours before operation the danger of the development of acidosis shortly after operation is reduced. Such a meal may consist of 250 c c of orange juice and an average sized helping of oatmeal with milk. A dose of iodine

should be administered with the meal. Such a meal will usually be out of the stomach by the time of operation. For a few days following operation, the caloric expenditure of the individual, which was already high before operation, is still further accelerated. Hence the caloric intake should be maintained at as high a level as possible in the immediate postoperative period. This is usually most conveniently done by administering a mixture of equal parts of milk and cream, which should be begun as soon as vomiting ceases.

Patients who are in good condition before operation can withstand vomiting of from eight to 10 hours' duration without a serious drain on the body reserves. Should vomiting continue beyond this time, fluid should be administered subcutaneously in the form of 10 per cent glucose at the rate of 3000 c c in 24 hours. This not only provides fluid but prevents the development of an acidosis. The glucose should contain iodine in any suitable form. The patient should receive at least one dose of iodine in the 12 hour period immediately following operation. Rarely is it necessary or desirable to give fluid intravenously after operation. Whenever the circulation is so poor that fluid is not absorbed from the subcutaneous spaces, the condition of the patient is usually so critical that putting it directly into the circulation will not accomplish the desired result and has the further disadvantage of overloading the right side of a heart which is already failing. Moreover, when reactions occur, as they do occasionally even in hospitals where great care is used in the preparation of glucose, they are less apt to be fatal if the injection has been given subcutaneously than if it has been given intravenously. What has been said about the intravenous administration of glucose applies also to the intravenous administration of normal salt solution and various iodine preparations. The majority of patients do not require the parenteral administration of fluid. We have seen patients who were in excellent preoperative condition, and who otherwise would have had mild postoperative courses, suffer greatly because of reactions following the parenteral administration of fluid on a standing order. We know of several instances in which the needless administration of fluid by the subcutaneous and intravenous routes appeared to be a factor in the death of patients. In the postoperative management of our patients we deal with many different interns on many different services and our chief trouble is not to get them to do enough, but to keep them from doing too much.

3 Treatment of Complications **Cardiac Irregularities** The indications for thyroidectomy are virtually the same when cardiac irregularities are present as when they are absent. This means that in the absence of other untoward signs, we ignore cardiac irregularities in gauging the risk of operation. Auricular fibrillation in particular is common, both preoperatively and in the immediate postoperative period, and is of itself almost never a cause for alarm. Transient attacks of paroxysmal tachycardia are more serious, because of greater associated cardiac embarrassment. Actual cardiac decompensation at the time of operation, of course, increases the

risk considerably, although it is rarely necessary or advisable to carry out operative procedures when the heart is failing. It is still not definitely established whether digitalis and quinidine are of any value in the treatment of cardiac irregularities accompanying toxic goiter. Plummer still insists that digitalis is harmful and others, that it is a great help. We do not use digitalis in toxic goiter even in the presence of auricular fibrillation, because it has seemed to do no good and in some instances to embarrass rather than aid the heart. This applies particularly to the immediate postoperative period, during which some surgeons use it routinely for marked tachycardia with or without the presence of auricular fibrillation.

Tetany and Paralysis of the Vocal Cords. In the immediate postoperative period it is necessary to be on the watch for tetany and paralysis of the vocal cords. Tetany is comparatively rare and usually becomes evident on the second or third day after operation. When properly treated it is never fatal. It is rarely necessary to use the parathyroid hormone, calcium by mouth usually being sufficient. If an emergency arises, it can be controlled by injection of calcium intravenously. The main thing is to be constantly on the watch for tetany. Its incidence bears a direct relation to the extent of the surgical procedures, being more common in the more extensive operations. Since tetany is one of the most serious complications because it is usually permanent and there is no preparation of the parathyroid hormone which works indefinitely, we are skeptical about the wisdom of performing so-called total thyroidectomies which have been advocated by a few surgeons.

Paralysis of the vocal cords is fairly common and its incidence (from 5 to 15 per cent) appears to be related to the skill of the surgeon. In most instances it is unilateral but in rare instances is bilateral. In about half of the cases the paralysis is evident as soon as the patient awakes from the anesthetic, but in the other half does not become evident for from 12 to 36 hours after operation. It is usually associated with edema of the larynx which makes breathing difficult for from two to four days. This difficulty is relieved by inhalations of compound tincture of benzoin and a tracheotomy is almost never necessary even in patients with paralysis of both cords. It is most unusual for a vocal cord paralysis to be the cause of death following operation, although, by the increased muscular effort in breathing and the interference with sleep which it causes, the recovery of a very sick patient may be delayed.

It is of interest to see how the application of the principles outlined has affected the mortality from thyrotoxicosis in a large municipal hospital. Through the cooperation of Dr Frederick Tice and other members of the staff, it has been possible to make a study of the disease at the Cook County Hospital in Chicago. Among the cases followed by other observers the mortality from thyroidectomies for exophthalmic goiter between the years 1931 and 1933 varied from 12.7 to 13.3 per cent, with an average mortality of 13.1 per cent (total of 305 cases). The mortality from toxic adenoma

during the same period varied from 8.1 to 12.1 per cent with an average mortality of 9.8 per cent (total of 102 cases). The average mortality for non-toxic adenoma during the same period was 4.1 per cent (106 cases) and for simple goiter, 2.6 per cent (38 cases).

In the patients with exophthalmic goiter whom we have personally followed during the period 1932-1934, the mortality has been 4.2 per cent (72 cases). The number of patients with other types of goiters is too small to base conclusions on, there having been 12 cases of toxic adenoma with no deaths and 14 cases of non-toxic adenoma with no deaths. It may be seen that the mortality among the patients with exophthalmic goiter that we have followed is the same as that in the group of patients with non-toxic goiter followed by other observers. The reduction in the operative mortality in exophthalmic goiter has been accomplished without any change in surgical personnel and without any significant change in surgical technic. In interpreting these data it must be borne in mind that the operative mortality in large municipal hospitals where all general surgeons of varying skill do goiter surgery can probably never be reduced to the level reported from highly specialized private clinics where only two or three men of unusual skill do all the thyroid surgery. Our mortality is still much too high and we hope to reduce it further, but at the present time it is probably as low as in any large city hospital and lower than in many of them.

This brings up the question of specialization in goiter surgery. In the training ordinarily considered adequate to prepare a man to do general surgery, so few goiter operations are performed that sufficient opportunity is not provided for the development of surgical judgment and skill. If institutions wish to reduce their goiter mortality to the lowest possible rate, they must be prepared to have all of their thyroid surgery done by only a few men who by experience have learned to appreciate the importance of adequate preoperative preparation of their patients and have developed speed and gentleness in their surgical technic.

It is of some interest to review briefly the case histories of the patients who died in order to consider how their lives might possibly have been spared. In the first patient the basal metabolism dropped from about plus 50 per cent to about plus 25 per cent during the administration of iodine although he did not gain any weight. The preoperative course of the disease was complicated by an upper respiratory infection which it was thought, however, had cleared up at the time of operation. The disease did not appear to be particularly severe. He seemed nervous as soon as he awoke from the anesthetic and his pulse rate for the most part was 140 or over thereafter. His temperature gradually rose to 105 just before death. It was possible to detect bronchopneumonia on physical examination 13 hours before death, which occurred 60 hours after operation. In the second patient the disease was complicated by diabetes. Although the metabolism was not very high (from plus 30 to plus 40 per cent), it did not show

any reduction during the administration of iodine. His preoperative course was also characterized by frequent attacks of diarrhea and a loss of 14 pounds in weight, caused by inability to get him to cooperate enough to eat the food ordered. He created the impression of being unable to stand much and his fellow patients had predicted that he would not survive the operation. Following the thyroidectomy he had a rather stormy course with a marked tachycardia and several insulin reactions. He appeared, however, to be doing fairly well three to four days after operation, only to become worse in association with the development of lobar pneumonia from which he died five days after operation. The third patient entered the Cook County Hospital August 1, 1933. Although his basal metabolism was only about plus 40 per cent, emotional instability and muscular weakness were well marked. During the administration of iodine his metabolism, instead of dropping, rose to about plus 58 per cent and the manifestations of the disease became more marked. It was felt that he could not stand a hemithyroidectomy and, against our advice, both superior poles were ligated September 11. Following operation his metabolism did not drop but he did lose five pounds. The inferior poles were ligated against our advice October 7. Again, his basal metabolism did not drop but he did lose another nine pounds and developed a paralysis of the left vocal cord. Iodine was omitted November 5, following which his metabolism rose to plus 70 per cent. He was sent home November 26 and reentered the hospital January 3, 1934. When iodine was readministered his metabolism dropped only slightly to plus 60 per cent, but he did gain 13 pounds. A left hemithyroidectomy was done March 13, but it was greatly prolonged by the technical difficulty caused by the scar tissue from the first operations. His pulse rate rose from 110 to 160 during operation and remained at this level until three hours after operation when it became too weak to count. His temperature gradually rose to 103 and his respirations to 40. He became irrational six hours after operation and died an hour later.

In the first patient it is possible that operation was performed too soon after the upper respiratory infection. The second and third patients were not suitable risks for operation and it should either have been postponed still longer or an attempt made to reduce the intensity of the disease with roentgen-ray treatment before proceeding with surgery. The technical difficulties of operation contributed perhaps to the death of the third patient, but in these two deaths we ourselves must bear a large share of the responsibility, while in the death of the first patient the exact cause is uncertain. These deaths illustrate the main point, namely that operative mortality depends in large measure on the condition of the patient at the time of operation. The patient's life is saved in the preoperative period and very little can be done to avoid a fatal outcome after operative procedures have already been carried out. Success in the treatment depends upon intelligent co-operation between physician and surgeon.

SUMMARY

The two most important factors in determining the risk of thyroidectomy for exophthalmic goiter are the preoperative condition of the patient and the skill of the surgeon. In preparing patients for operation great attention must be paid not only to the administration of iodine but also to the administration of a diet sufficiently high in calories to make the patients gain weight, to the control of emotional instability and to rest. The severity of the postoperative reaction appears to be related more directly to emotional instability than to any other factor. There should be no hesitation about postponing operation until the condition of the patient appears satisfactory.

Selection of the time of operation is more important than the selection of the type of operation, although the thyroidectomy should be performed in at least two stages in all patients in whom there is any doubt about the ability to withstand operative procedures. Ligations of arteries do not appear to affect the intensity of the disease.

Success in the treatment depends upon intelligent cooperation between physician and surgeon. Miracles can not be performed in the postoperative period and the time to prevent postoperative crises is in the preoperative period.

By applying the principles outlined to the preoperative treatment of exophthalmic goiter at the Cook County Hospital in Chicago it has been possible to reduce the operative mortality from 13 per cent to about 4 per cent without any change in surgical personnel or surgical technic.

In order to keep the operative mortality at the lowest possible rate, hospitals should not only pay more attention to the preparation of such patients for operation, but should relegate their thyroidectomies to a few surgeons who have developed good judgment, speed and gentleness and not to general surgeons who have had little opportunity to perfect the technic of thyroid surgery or to learn contraindications to operation.

We are greatly indebted to Dr. Frederick Tice and other members of the staff of Cook County Hospital for the privilege of making many of the observations referred to.

THE ALTERNATIVE TO REVOLUTION *

By GLENN FRANK, *Madison, Wisconsin*

THE air is, at the moment, filled with premonitions of profound change in the political, social, and economic life of the United States

Many Americans are sincerely fearful that we may rush into changes that will bring our traditional order of private enterprise and political liberty to a decisive and disastrous end. And they see no matured alternative around which grave doubts do not swarm. These Americans have no personal or political axes to grind by the expression of this fear. Their concern is genuine.

A few Americans, without this sincerity of concern, are attempting to further personal and partisan interests by branding even the simplest and most obviously sensible suggestion of change as part of a sinister plot to communize the nation. Save to express my contempt for such tactics, I shall waste no words on these ventures in shoddy politics and sordid economic propaganda. Sooner or later, the bogey-monger, whether hailing from the ranks of radicalism or reaction, is strangled by his own insincerity.

But, whether sobered by calm analysis or stimulated by faked alarms, the national mind is anxiously speculating on the turn affairs may take in the days ahead. Can we ride the storm without basic changes in the traditional order of American life and enterprise or are we in for a drastic reordering of our political and economic arrangements? I want to air this issue with as much candor and realism as I can muster.

No simple and single answer to this question is possible. The forces of change now in operation may be dammed up by inflexible tradition until they break the dykes with a rush of revolutionary energy or they may be directed by flexible intelligence into a process of social reconstruction that will give fresh significance and assured stability to our national future. Because I believe that the future and fortune of all of us now living will be determined by the outcome of the battle royal that is now on between the forces of inflexible tradition and the forces of flexible intelligence, I have chosen to chart the issues of this battle in terms of the current national situation.

I am convinced that profound historic change impends in the life and enterprise of our time. I am not at all sure of the direction this change will take. We may be in for a long retrogression or we may be on the threshold of renaissance. The blackening of the skies that began in 1929 may have heralded a permanent eclipse of the national genius or these may be but the grey hours before a social sunrise that will warm and illumine our lives where transient disaster has chilled and darkened them. In either case, the America of tomorrow will, I am convinced, be radically different from the

* Address at the banquet of the American College of Physicians, Chicago, April 19, 1934

America of yesterday's textbook or of today's newspaper. And what that America will be like will depend primarily upon whether the forces of inflexible tradition or the forces of flexible intelligence direct our affairs in the days immediately ahead.

Our national life is just now in the fourth phase of a sequence of events that has before in history brought whole peoples to the social crossroads where decisions affecting their destiny have had to be made. Unless I grossly misread the meaning of the last two decades of American history, four distinct developments have brought the American social order to its present critical juncture.

First, old philosophies and old procedures which had long dominated our political, social, and economic life fell into varying degrees of futility through the failures of American leaderships to keep them progressively adjusted to the new circumstances of this new age of science, technology, and plenty.

Second, while these old philosophies and old procedures were falling into futility, new philosophies and new procedures, more alert to the needs and better adapted to the nature of this new age, were being patiently and unobtrusively elaborated by scientists and seers whose historic mission it is to be the unofficial statesmen who, in freedom from the clamor of constituencies and the compulsions to compromise blaze new trails of thought and action which the official statesmen may later follow if they will.

Third, a long period of manifest maladjustment between the old policies and the new problems of American life ensued, but, despite the heavy hand this maladjustment laid upon the lives of men, the masses of Americans clung uncritically to the doctrines of the fathers in matters political and economic.

Fourth, in the wake of the world-wide economic collapse, from one end of the United States to the other, men have been shaken out of the sterile serenity that marked their mood in the days of the pathological prosperity of the Coolidge era, with the result that today they no longer display reluctance to question even the major assumptions upon which their life and enterprise have long been organized.

It is the mood of this fourth phase that makes critical the present juncture in American affairs. The present temper of the American mind differs vividly from its pre-depression temper. In the days of our phantom prosperity we were sleek and self-satisfied. We were well-fed and wanted nothing so much as to be let alone. We were impatient of those queer persons who were forever raising disturbing questions about our political, social, and economic policies. As if anything could possibly be wrong with a civilization that was paying such excellent dividends! The result was that, throughout the prosperity period, we turned deaf ears to the advocates of political, social, and economic readjustments that might well have averted the disaster that has darkened our lives since 1929.

Even I, mild and modest commentator that I am, found myself damned as a dangerous citizen by certain Wisconsin politicians and a few Wisconsin industrialists, during the 1932 campaign, for having advocated ideas which have since been hailed as the soundest of sound business sense by that notoriously red organization, the United States Chamber of Commerce.

As long as the nation was on its economic joy ride, new ideas had hard sledding. Almost the sole exception to this was the lush growth of bootleg religions and the rise of an apostolate of fakirs who led thousands of otherwise intelligent Americans to believe that, in their wistful quest for the deeper meaning of existence, they could suck the juices of a living gospel from the dead rinds of ancient superstitions or the green stalks of bogus psychologies. It may be that mankind will always rebel in this irrational sort of way against an era that becomes so exclusively absorbed in the goods and chattels of a crass prosperity. At any rate, aside from this single exception of the gullible embracement of improvised religions, the American mind betrayed a baffling immunity to new ideas as long as the economic skies were bright. Until the chill and shadow of the market collapse fell upon us, we were smug to the point of blindness to the basic drift of our civilization. It would be difficult, I think, to put one's finger upon even a single truly productive new idea in politics or economics which swept the mass mind while the phase of prosperity was on.

An old Scotchman, seeking to account for this seeming immunity of the American mind to new ideas, said, "The heather was wet!" And anyone who has tramped over the hills of Scotland knows that when the heather is wet fires do not sweep easily across the fields. But today the situation is the exact reverse. The heather is not wet today. The heather is dry! Disillusionment has done its perfect work. The man in the street, along with the man in the furrow, is straining at the leash of old dogmas of politics and economics that have failed to keep hunger from his stomach, cold from his body, and fear from his heart. The tethers of a thousand traditional loyalties have slipped during the last five years as men have watched the very ground stakes of their social order loosen. And from one end of the United States to the other men are today fumbling blindly for some lead out of the blind alleys into which blind leaderships led them.

Such a mood is at once a grave danger and a great opportunity. A grave danger if irresponsible demagoguery dominates it! A great opportunity if responsible statesmanship directs it!

In its present mood the mass mind is willing to follow responsible statesmanship. It would prefer to follow responsible statesmanship. It may follow irresponsible demagoguery. And it lies wholly with statesmanship to say which turn affairs shall take.

The American mind, unless I grossly misread its present mood, will take counsel of its patience while a Roosevelt gathers power unprecedented into his hands and cuts the red tape that normally binds government to the hitching post of inaction. But it will not unduly prolong its patience. There is a latent impatience moving restlessly close under the surface of the liberal patience Americans generally have displayed during the difficult days of the last five years. The mass mind expects constructive action and creative results to follow the freedom to act which its mood made Congress make possible something more than a year ago.

And—let us speak plainly—the mass mind expects something more than a Red Cross statesmanship that momentarily salves the economic wounds of the time and subsidizes into transient silence a growing army of the legitimately discontented. It expects careful but courageous readjustments of our political, social, and economic policies that will enable us to take full advantage of the fruits of this new age of science, technology, and plenty.

It was for this, and this alone, that we adjourned so much that is traditional in our democracy. It was for this, and this alone, that we set up a crisis government under which a Roosevelt is given in peace time powers far beyond the powers given to a Wilson in war time. And the mass mind will hold this crisis government to strict accountability. If the fruits of this freedom to act, which the mass mood made possible, should fail visibly to ripen, the mass mind will turn inevitably to an alternative leadership. And the danger is that it might be none too discriminating in its selection of the alternative.

One thing should by now be clear, alike to the Roosevelt administration and to the political opposition, and that is this. We are past the point at which beating the tom-tom for obsolete traditions of politics and economics can either satisfy the mass mind or bring recovery and stabilization to our national life.

We still have time to choose between guided reconstruction and unguided revolt!

I use the word "revolt" instead of the word "revolution" because there is a basic difference between the two. This distinction was dramatized by the Duc de la Rochefoucauld as he stood with King Louis watching the Parisian mob storm the Bastille in 1789.

"This is revolt," cried Louis.

"No, Sire," said Rochefoucauld, "it is revolution."

Revolt was there, of course, but Rochefoucauld was right in reminding Louis that he was watching the profounder process of revolution in which his people had set deliberately out to readjust the old tools of government, which were obsolete, to the new tasks of government, which were obvious. And this, as Rochefoucauld saw, was a more fundamental thing than mere revolt. It was a far-reaching process of social readjustment in which revolt was but an incident that might or might not take place.

There can be revolt without revolution. There can be revolution without revolt. In fact, the greatest revolutions are not marred by revolts. We do not want revolt in the United States. And, unless the American intelligence wholly abdicates, we can face difficulties far more drastic than we have yet known without revolt. But, unless we are willing to run the risk of a lapse into complete social and economic chaos, we cannot avoid revolution, if by revolution we mean what we should mean, namely, evolution under the guidance of an intelligence that is neither enslaved by inflexible tradition nor dragged at the heels of ill-conceived change.

Changes are forever taking place in the life and enterprise of living

peoples When change stops we may know that the genius of a people has gone cold and a civilization has died We cannot escape the fact of change, no matter how stubborn our orthodoxies The problem is not to prevent change but to pilot it to productive ends

If flexible intelligence were always at the helm, we would keep our social institutions progressively adjusted to the changing circumstances that are inseparable from a living civilization And the result would be that society would never come to dramatic turns in the road where it had to undertake wholesale readjustments of its policies to situations leadership had too long neglected But, unhappily, this is not the way the race has functioned to date There is always a lag between the swiftly changing life and the slowly changing institutions of a people And it is this fact of lag that gives rise to the sort of crisis that has frozen the fountains of our enterprise for the last five years

It is right that there should be some lag Otherwise our institutions would be in a continuous St Vitus dance of change that would make ordered life and productive enterprise impossible We do not want our institutions to chase down the street after every Pied Piper who has snared a new notion from the cloudland of theory Most new ideas are wrong By which I mean that the race is lucky if experience ratifies as true one out of every thousand new theories it evolves Most of the ideas that have survived the stress and storm of the centuries are right I mean the ideas that have survived with vitality, not the ideas that have merely stayed on as cadavers to poison the intellectual atmosphere All of which means that we must build our lives, individual and institutional, mainly on ideas the race has hammered out on the anvil of experience No generation can expect to add more than a little to the wisdom of its ancestors

It is not a matter of deciding whether we shall cling to tradition or cultivate change Tradition and change are not alternatives They are two indispensable elements of civilization that must be kept in the proper relation

A certain amount of social lag is desirable in the interest of continuity and stability We want our institutions to maintain a saving continuity We do not want our churches, schools, and economic establishments taken to pieces every evening at sundown and put together again in some new pattern every morning at sunup But we must remember that our institutions must maintain continuity with the future as well as continuity with the past Otherwise they will some day find themselves tenantless and dark in the midst of a generation whose allegiance they no longer command We want our institutions to have stability But their stability must be the equilibrium of steadied action not of mere inertia Otherwise they become but so much waste lumber cluttering the current scene A certain degree of lag between institutional change and social change is, therefore, necessary if civilization is to be kept a going concern

If, however, we permit the policies and procedures of our institutions, under the lordship of inflexible tradition, to lag too far behind the changes that are taking place in the society they were designed to serve, glaring maladjustments occur. These maladjustments produce a social instability. And this social instability may at any moment lead an otherwise patient people blindly to break continuity with the sound as well as the unsound values of the past.

This, I fear, is the pass to which we have permitted American affairs to come!

I have not come to this conclusion from reading the inflammatory manifestos of radical agitators. I have been driven to this conviction by such eminently respectable documents as the report of former President Hoover's Research Committee on Recent Social Trends. It is, I submit, impossible for any literate American to read the two major volumes of this Hoover report, together with the subsidiary volumes that elaborate its findings, without realizing that our American civilization has become, both in its nature and in its needs, a radically different civilization from the American civilization in terms of which our forefathers determined the major patterns and designed the major institutions of our political, social, and economic life. The resistless forces of physical science and industrial technology have completely remade the civilization going on outside the walls of our institutions. The problems that this changed and changing civilization is today putting to government, to business, to industry, to finance, to the church, to the school, and to the family, as these problems are assembled and analyzed in this Hoover report, are drastically different from the problems that faced us even a generation ago.

And the report of this Hoover committee dramatizes, as no document before or since has dramatized, the fatal lag between our old policies and our new problems. This monumental research in social trends boils down to this: most of the major patterns and most of the major institutions of our political, social, and economic life were designed in terms of an American civilization in which (1) the scale of enterprise was small, (2) the relationships of life simple, and (3) the tempo of affairs slow. But now these institutions must function in and serve an American civilization (1) in which the scale of enterprise is no longer small, but vast, (2) in which the relationships of life are no longer simple, but complex, and (3) in which the tempo of affairs is no longer slow, but swift.

The overshadowing problem of this generation is to keep the response of our institutions to the sort of sweeping changes reflected in this Hoover report a guided reconstruction without revolt. And I submit that nothing save a flexible intelligence, mediating wisely between the forces of tradition and the forces of change, can possibly insure this result.

I give you two immortal pronouncements, rich in statesmanlike guidance to a people, like ourselves, caught in the swirl of a rapidly changing civilization—one from John Stuart Mill, the other from Viscount Morley

"The future of mankind will be gravely imperiled," said John Stuart Mill, "if great questions are left to be fought out between ignorant change and ignorant opposition to change"

This sentence might with profit be printed on the title pages of the 1936 campaign textbooks of both the Republican and Democratic parties!

"Great economic and social forces flow with tidal sweep over communities only half conscious of that which is befalling them," said Viscount Morley "Wise statesmen are those who foresee what time is thus bringing, and try to shape institutions and to mould men's thought and purpose in accordance with the change that is silently surrounding them"

It is this emancipation from inflexible tradition and this exercise of flexible intelligence, expressed and exemplified by the John Stuart Mills and the Viscount Morleys, that constitutes the most crying need of this distraught time It is this sort of judgment and action that the schools, colleges, and universities must prepare men to bring to those readjustments that have become imperative as a result of the silent but sweeping revolution that science and technology are working in the political, social, and economic arrangements of American life

The question is not what we should think about some hypothetical "revolt" that the bogey-makers picture as stealing upon us unawares, like a thief in the night, hidden in the cloak of some professor who has had the insight to see and the courage to say that American capitalism must effect a sounder distribution of buying power if it wants to survive, or lurking in the surplice of some clergyman who has come to suspect that maybe war after all is not the whole will of God

The question is what we purpose to do about the actual "revolution" through which the United States is now passing, the revolution induced by physical science and industrial technology, the revolution so adequately reported and ably documented by the Hoover Research Committee on Recent Social Trends

It is no easy matter to bring flexible intelligence to bear upon public affairs in so confused a time A thousand pressures—political, social, professional, and economic—come continually upon us to spend our energies fighting the windmills of imaginary threats of revolt instead of bringing our intelligence carefully but courageously to bear upon that guided reconstruction of American life which is, in my judgment, the only alternative to the increasing insecurity and ultimate collapse of our social and economic orders

There are frightened reactionaries who are sure we are drifting into Communism There are frightened radicals who are sure we are drifting into Fascism We may, I think, take both these fears with a grain of salt Nations never *drift* into either Fascism or Communism Nations go Fascist or Communist only when the soil is thoroughly prepared for the seed and when there is behind the Fascist or Communist push a capable, clear-headed, closely knit, and rigidly disciplined group able to get its hands quickly on

the levers of military and economic power. There is nothing in the American picture to indicate that we have reached such a point. And there is nothing inherent in the situation that need ever lead us to such a pass.

We are not an easily inflammable people. Even the more moderate movement of American Socialism has not made dramatic headway during the last decade. In 1920, Eugene Debs polled more than 200,000 votes in New York State and more than 900,000 votes in the country as a whole. Twelve years later, in 1932, in a time of incredible economic hardship, when the wine of discontent was everywhere in ferment, the able and persuasive Norman Thomas polled only 175,000 votes in New York State and only about 800,000 votes in the country as a whole.

I am aware that, in 1932, a large protest vote, that might under more normal circumstances have gone to the Socialist candidate, went to Franklin D. Roosevelt. But that hardly argued the imminence of rebellion, for what has seemed to some the radicalism of Rooseveltian policies has come into the picture since the election. I submit, therefore, that both the low vote of Norman Thomas and the high vote of Franklin D. Roosevelt indicate that we are not an easily inflammable people. And, for this reason, I refuse to be stampeded by the alarmists.

I believe that the American tradition of private enterprise and political liberty, if now corrected in the light of experience and wisely adjusted to the new requirements of an age of plenty, will be in the forefront after all of us now living have long been dead and the Fascisms and Communisms of the moment have become the relics of dead yesterdays. I hope you did not overlook the "if" clause in that sentence, for candor compels me to say that I could not so confidently predict the survival of capitalism and democracy unless I made the prediction contingent upon our willingness to face fresh problems with fresh minds and to rethink and recast our basic policies respecting wages, hours, prices, profits, and control, as well as the processes of democratic self-government, in the light of the new circumstances of this new age of science, technology, and plenty.

The blunt truth is that the fate alike of private enterprise and of political liberty is wholly dependent upon the flexibility of intelligence we can muster in the decade immediately before us. There is no area of our common life—whether it be politics, economics, or religion—in which the current situation does not cry aloud for flexible intelligence.

Certainly flexible intelligence is needed in the field of politics. Political action has lately assumed a new importance for the American future. Donn Byrne, weaver of colorful tales of his beloved Ulster, once wrote, "I have never seen a government that brought heavier apples to the trees or heavier salmon to the rivers or a more purple heather and for this reason politics means nothing to me." Strange doctrine for an Irishman! It was doubtless temperament that led this Celtic prose-poet to assume so cavalier an attitude toward politics. It must be admitted, however, that, until lately, signs were not wanting that we might be passing out of the age of politics,

in the old sense of politics. The tone and temper, if not indeed the very structure, of our society were increasingly determined by non-political forces. Forces of physical science! Forces of industrial technology! Forces of cultural reevaluation! These, rather than the decisions of politicians, were the forces that, for half a century, had been making, unmaking, and remaking civilizations throughout the Western world. And yet, at the moment, American destiny is, I am convinced, strangely dependent upon the quality of political thought and action we can contrive to bring to the direction of our industrial and international affairs in the days ahead.

We cannot expect more than transient and insecure phases of recovery until, as I have suggested, we have rethought and recast our basic policies respecting wages, hours, prices, profits, and control in terms of the new circumstances of this new age of science, technology, and plenty, and until we have achieved a rationalized program of world relations. I have been driven reluctantly to the conclusion that, as American life is now organized, we shall not find in the ranks of business, industry, and finance a leadership that can effect promptly enough and apply widely enough those basic readjustments of economic policy that events are forcing upon us as the price of recovery and stabilization, and that, for the time being at least, the initiative for these readjustments must come from political leadership despite the dangers inherent in any undue extension of political sovereignty over private enterprise.

It is, I suspect, a flexibly intelligent political leadership, and it alone, that can break the impasse to which the forces of science and technology, in stubborn conflict with obsolete political and economic policies, have brought the American social order.

Certainly flexible intelligence is needed in the field of economics. I am singularly unmoved by the wolf cries of the Dr. Wirts who see a bolshevik behind every bush. But I am not blind to the fact that the fate of private initiative is definitely at stake in the whirl of affairs at Washington today. Individualism, rugged and otherwise, is on the run. This throws an unprecedented challenge to the sincere friends of private initiative. I count myself among the friends of private initiative.

I am not at all enamored of the prospect of having my own and the nation's life ordered about by bureaucrats. I should be reluctant to see the intricate processes of the nation's economic enterprise put at the mercy of the quality of intelligence that American politics has, by and large, been able to recruit during the last quarter century. I do not believe that the complex economic life of the United States can ever be run effectively from Washington. I doubt the wisdom of having political persons dictate in detail the risks and routines of American business and industry. And this doubt survives even the muddling mismanagement of the nation's enterprise by many of the leaders of business, industry, and finance in the decade before 1929.

But I am, I hope, a realist. And I set it down as a deep conviction that a sustained study of the passing show has forced upon me that if the freedom of private initiative dies on this continent in the next ten years its friends will have been responsible for its death because they failed to bring a flexible intelligence to its operation in the last ten years. For the last ten years, private initiative has been doing its level best to commit suicide. Under such circumstances, the more a statesman believed in private initiative, the more he would be moved to grab private initiative by the collar and seek to discipline it before it took the last fatal leap.

There is no dominant body of either Fascist or Communist thought in the United States. Franklin D. Roosevelt does not want to be a dictator. But neither an intelligent president nor an impatient people will stand idly by and see a whole civilization sink just in order to preserve the dogma of private initiative.

It lies, I think, with the leadership of American business, industry, and finance to say just how far infringements on private initiative shall permanently go in the readjustments imperatively before us. If the leadership of American industry will now pool its varied genius in a nationally integrated effort to work out and to put into effect as promptly as possible wage, hour, price, and profit policies that will spread the normal national income widely enough to make the toiling millions a dependable consumer market for the maximum output of our machine economy, if the leadership of American industry will make the increase, the enrichment, and the stabilization of life for the millions its first obligation, and if the leadership of American industry will expect private profit to come, as I think private profit should come, only as a by-product of and compensation for its statesmanlike administration of the social function of industry, neither the President nor the Congress will spend much time trying to fasten any dictatorship on American industry. And, incidentally, industrialists will find the size and the security of their total profits increased, even if the profit margin on the individual article or action is narrowed. If the leadership of American finance will produce a banking system that will serve instead of sink the nation's enterprises, no one will lie awake nights to devise halts and hobbles for bankers.

Nearly everybody in America prefers private initiative—if it will only deliver the goods. The economic disaster that has befallen us is not, in my judgment, inherent in the nature of private initiative, but is the result of its gross mismanagement. The preservation of private initiative will depend wholly, I think, upon its practitioners' bringing flexible intelligence to its operation in this new age of science, technology, and plenty.

Certainly flexible intelligence is needed in the field of religion if we are to preserve, as a sweetening and savoring factor in our national life, certain priceless values that are gravely endangered in this phase of social disillusionment. It may seem to some beside the point to inject the problem

of religion into this study of the social and economic renewal of American life. Let me tell you why I think it is not.

Despite the protestations of a few disgruntled politicians and short-sighted business men, the old order of catch-as-catch-can politics and economics is as dead as the dodo. The traditional order of American life and enterprise has come definitely to a cross roads where we must decide between a voluntary cooperation of all classes for common ends and submission to a regime of compulsion that will impose upon us political and economic arrangements that will break the stalemate of the last five years.

No authentic American wants to see compulsion come. The essence of the American spirit is its love of freedom. But there are only two regimes under which free men can survive: (1) the virtual anarchy of *laissez faire*, or (2) control through wide and willing cooperation. In a simple society *laissez faire* works well and free men enjoy stretching their powers unhindered. In a complex society *laissez faire* does not work well and sooner or later free men find their freedom worthless in the midst of a crashing collapse of their economic order.

Having practiced the virtual anarchy of *laissez faire* so long, free men, when caught in a collapse like the crash of 1929, rush distractedly about with next to no disciplined capacity for that prompt cooperation for common ends which the enterprise of recovery and stabilization requires. And, in their distraction, they all too often fall wistfully into the arms of dictatorship. This is the story of Italy. This is the story of Russia. This is the story of Germany. This may become the story of France. This may happen in England. Will this be the story in the United States? It may!

There is just one thing that will prevent our surrender to an increasing compulsion. And that is a nation-wide crusade, essentially religious in its passion and purpose, for the universal cooperation of individuals, groups, and classes in the determination of policy in terms of the common welfare of the whole nation. The total combined forces of Catholicism and Protestantism, augmented by all the anonymous religious concern that may reside in our people, should now be brought to focus on the stimulation of a vigorous faith in and active effort toward a nation-wide reconsideration and redirection of our political, social, and economic orders through a vast popular cooperation in which personal and class interests are adjourned and the increase, enrichment, and stabilization of life for the millions made the dominant concern.

Until the economics of a New Deal are fortified by the religion of a New Deal, we shall continue to be victimized by the predatory trickeries of the trader and the polite treasuries of the politician. And this social passion for the common welfare of the nation must be more than a crusade for secular uplift. It must sink its roots in the soil of a faith that lies beyond economics. The future of American religion and the future of the Ameri-

can social order are more intimately interlocked than many, in the facile modernism of their reasoning, have been inclined to think

It is disclosing no secret to say that the fountains of religious concern have tended to go dry while for the last half century we have wandered in the far country of materialism, concentrating our energies upon laying the physical foundations and elaborating the instruments of our machine economy which today stands stalled in our presence

Many are rightly concerned over the widespread secession from belief in God that has been increasingly evident as the machine age has come to maturity I know the barbarisms and indignities that fanatics have perpetrated in the name of God I know the innumerable caricatures that shortsighted men have drawn of His countenance, reading their own lusts and limitations into His purposes I know how often whole peoples have projected either the tyranny or the tenderness of their social orders into their concept of God I know how often sinister interests have sought to use God as a smoke screen for their anti-social adventures But I know also the myriad army of saints and seers whose lives, illuminated by the light of His countenance, have been given to fertilize the soil from which the freedom, as well as the faith, of the race has flowered And I am convinced that a civilization that exiles an exalted concept of God from its heart dries up one of the major well-springs of its power

I agree with the sometimes exquisitely pagan Edna St Vincent Millay when she writes

Not Truth, but Faith, it is
That keeps the world alive If all at once
Faith were to slacken—that unconscious Faith
Which must, I know, yet be the corner stone
Of all believing—birds now flying fearless
Across would drop in terror to the earth,
Fishes would drown, and the all-governing rems
Would tangle in the frantic hands of God
And the worlds gallop headlong to destruction

Remote as their relation may seem to the practicalities of social and economic renewal, here are questions quite as vital to the national future as industrial codes and tariff agreements How shall the forces of religion make God again believable to men who have lost all faith in any lordship of life? How shall we save men of this generation from a corrosive cynicism? How shall we help disillusioned men to recapture a courageous confidence that life is not just a blind dance of atoms, but a meaningful adventure worthy of deathless objectives?

I shall not presume to make any final answer to these questions that have harrassed mankind since the infancy of the race But of one thing I feel sure few, if any, men are drawn to belief or driven into disbelief in God by the traditional dialectics of the theists and atheists Men's belief in God is broken or buttressed less by the arguments they hear than by the

way in which the social order, in which they have to live, breaks or buttresses their lives

A man whose life has been broken by the brutality of his fellows is less likely to believe in a beneficent God "Friends should be kind to a despairing man," Job is found to say in one of the modern translations of the Old Testament, "or he will give up faith in the Almighty" And Johan Bojer, in his "The Great Hunger," makes an old Norwegian farmer say, "I sowed my enemy's field with corn in order that God might continue to exist" And, from an ancient scripture and a modern tale, I bring you the conviction that men's belief or disbelief in God may be but a reflection of what society has done to their lives If we compel a man to live his life in a social order bereft of love and its sterner counterpart, justice, we must not be surprised if he has difficulty in believing in a God of love and justice We cannot expect a God of love to be wholly convincing in a loveless world And to ask men to believe in a God of justice when their whole lives have been blighted by injustice is, to say the least, optimistic

Men of flexible intelligence, concerned to renew and release the religious impulse as a factor in the reinvigoration of our national life, will not attempt to combat atheism or to cultivate a belief in God by sheer dialectics For men of flexible intelligence will know that the future of religion on this continent depends less upon the explanations of professors and the exhortations of parsons than upon the kind of social order we build on this continent

All of which means that, if the future of the social order is influenced by the quality of religion, the future of religion is also influenced by the quality of the social order If we are to achieve a balanced and meaningful civilization, therefore, we must work concurrently for the revitalization of religion and the reconstruction of the social order

And now my argument draws to a close I have exalted the virtue of flexible intelligence as the one hope of a stable and significant national future It remains only for me to say that, in my judgment, the stimulation and discipline of this flexible intelligence is the supreme contribution the schools, colleges, and universities can make to this disordered and distraught time Need I say that schools, colleges, and universities cannot stimulate and discipline this flexible intelligence unless they are themselves left free to bring flexible intelligence to bear upon the problems with which they must deal? Yes, I think it must be said, for we may be running into a time in which greater pressures than ever before will be brought to bear upon the schools, colleges, and universities to mould them to a pattern, to soft-pedal their researches into living realities, to tell them what they may and may not say

There are three major systems of political control now functioning in the Western world—Fascism, Communism, and Democracy Fascism and Communism have decided what they will do with their schools They have decided that the laboratory must take orders from the legislature There

are no dissenting professors in Italy. Dissenters have either suffered exile or bought their posts at the price of silence. There are no dissenting professors in Moscow. They are either nursing their wounds in Paris or picking up a precarious living as best they can elsewhere in the Western world. And now Hitler has put the sign of the Swastika on German scholarship. As Charles E. Merriam has suggested, it remains only for the democracies of the West to say that they will not tolerate differences of opinion to make it unanimous, and then we can blow out the light and fight it out in the dark, for, when the cry of intelligence is silenced, the rattle of machine guns begins.

EDITORIALS

CONTROL OF MEDICAL PRACTICE

Fairness, it would seem, demands, in any human transaction, that the rights of all parties shall receive due consideration. This principle should apply to the doctor-patient relationship, which is in effect the sale (when it isn't a gift) of medical care to the patient by the doctor. Both parties to the transaction are deeply interested. To the patient, it may be a life or death matter, to the doctor, a portion of his livelihood. Exploitation of either by the other is incompatible with sound ethics. Yet we have it on high authority that "all features of medical service in any method of medical practice should be under the control of the medical profession. No other body or individual is legally or educationally equipped to exercise such control." The patient is to take what he can get and be thankful. So-called organized medicine, an interested party, is to be the sole arbiter of how the public, the other interested party, can obtain its medical service. The public is to have no voice in the matter. The medical profession does not admit that anyone can tell it anything about these matters. Such an attitude by "organized medicine" is explicable only on the theory that the fear of state medicine has given it the jitters.

The statement that none is equipped educationally or legally to exercise control over medical service save the doctor will have to be supported by evidence. One might even question whether the doctor himself is fully equipped. What, for example, does he know in any expert way of the economic and social factors that enter into so complex a problem as the rendering of adequate medical care to the whole community? How much does he know of the prevention of disease? Precious little, and it will make a bigger hit with the public if he admits this and seeks advice, than if he assumes an attitude of omniscience. Even in the biologic aspects of his applied science, the physician leans heavily on the pure scientist, the physiologist, the biochemist, the physicist and others. Why should he not do likewise in the social? Perfection in the technic of any human enterprise is approached by the cooperation of all persons who have any intellectual contributions to make toward it. Improvement in supplying the community with medical care will be made by the collaboration of persons of varied interest, the health officer, the nurse, the social worker, the economist, the business administrator and others, as well as the man of medicine. Moreover, the public, that is to say the patient taken collectively, has a right to be heard.

Improved methods of rendering medical service, like advances in the science of medicine or any other science, will be found by experiment. Various types of medical practice, group practice, contract practice, industrial medical services, group prepayment plans, health insurance and any

others that seem to offer some promise, must be tried out. If experience shows them undesirable, they will naturally languish and die. It is to be remembered that a type of service that is suitable in one locality, or for one group of people, may be totally unsuitable for another. There must be a high degree of adaptability on the part of medicine, organized or unorganized, to meet various needs. In so far as it genuinely seeks to find better ways of furnishing medical care, it will gain public confidence. In so far as it adopts an attitude of fearsome standpattism, it will lose it. The profession ought always to remember that the doctor exists for the patient, not the patient for the doctor.

J H MEANS

AN ADVANCE IN THE DIAGNOSIS OF LEAD POISONING

The diagnosis of lead poisoning by its symptoms and by the signs found on physical examination is usually uncertain and needs for its confirmation a history of exposure to lead and the additional evidence procurable by laboratory tests. In adults the history of exposure to lead may be quite obvious as, for example, in those cases which arise among workers burning off lead paint with torches in enclosed spaces, or the determination of exposure may require considerable technical knowledge of industrial processes and not a little detective ability. The running down of the cause of a recent small epidemic in which the source of lead exposure was found to be the burning in stoves of discarded wooden battery casings impregnated with lead salts is an instance of the keenness that may be required in such an inquiry. In infants and children the patient may be able to give no assistance, and unless the physician is well aware of the frequency of lead poisoning at an early age he may not obtain from others the history of gnawing paint from window-sills or from toys, or of eating enamel flakes from cribs that would throw another light on the diagnosis of brain tumor, epilepsy, or appendicitis suggested by the symptoms.

The frequent lack of decisive symptoms, signs, or history in cases which nevertheless suggest the possibility of lead poisoning lends especial interest to any advance in the detection of lead poisoning by laboratory tests.

It was observed many years ago that the stippling of red cells exhibited a certain parallelism with the symptoms of active lead poisoning, and this simple laboratory method, that of studying the stained blood smear for stippled cells, remains one of the most valuable diagnostic measures. Stippled cells are, however, absent in as high as 30 per cent (Park) of cases of lead poisoning, and because of this inconstancy and because of a desire for a more quantitative method, the study of lead in the excreta and in the body itself has been pushed in recent years.

A primary difficulty arises from the fact that the presence of lead in the body or in the excreta proves only that exposure to lead has occurred and not that the defense mechanisms of the body have been overcome so

that active lead intoxication is in progress. Ingested lead may be held for the most part in insoluble forms in the digestive canal, and the presence of even considerable lead in the stools is not certain proof of lead absorption or intoxication. Lead excreted in the urine is, of course, derived from the lead in the blood stream and it may be assumed that its amount is usually roughly proportional to that of the circulating lead. The amount of circulating lead is undoubtedly the most important factor in determining whether or not damage to susceptible tissues will occur. The quantitative determination of lead in the urine should therefore be of great assistance in deciding the question of the presence of active lead poisoning. Certain difficulties, however, detract from the value of the method. In the first place, individuals exposed to lead may successfully store lead in their bones as rapidly as it enters their blood streams, they are instances of what might be termed compensated as opposed to active lead poisoning. The level of lead in their blood streams perhaps never reaches the height necessary to produce injury to susceptible tissues. Yet there is constantly some lead in their blood streams and constantly some lead excreted in the urine. Now the difference between the amount of urinary lead in such a case and in a case of active lead poisoning is usually less than a milligram in a 24 hour period. The necessary delicacy of chemical technic to dependably demonstrate difference of this order in the amount of urinary lead is not readily acquired. The method is valuable, therefore, when available, but for the majority of cases it is inapplicable because technical difficulties and expense have barred it from most laboratories.

The most positive evidence of active lead poisoning would evidently consist of quantitative analysis of the blood which would indicate the presence of an amount of lead incompatible with mere compensated lead poisoning. The amount of lead in the blood is too minute for present chemical methods. The application of spectographic analysis to blood ash has, however, proved fruitful (Shipley, Scott and Blumberg¹) and the results of this method so far constitute a distinct step forward. The delicacy of the method is so great that the absence of lead bands in the spectogram constitutes definite evidence of the absence of circulating lead. If lead bands are found an absolute quantitative estimation of the amount of lead present cannot be made, but there appears to be a difference in intensity which can be made use of in distinguishing between compensated and active cases of poisoning.

From a practical point of view, the new method has both difficulties and advantages. The expense of the apparatus and the necessary skill and experience for its use and for the interpretation of results will rule out the method for routine use in hospital laboratories. On the other hand, the manipulations involved in a single test are infinitely less time-consuming than are those needed for a quantitative chemical determination of lead in

¹ SHIPLEY, P. G., SCOTT, T. F. M. and BLUMBERG, H. Spectographic detection of lead in blood as aid to clinical diagnosis of plumbism, *Bull. Johns Hopkins Hosp.*, 1932, 11, 327-328.

the urine. A large city might be served by one apparatus in a central laboratory. The result may be obtained more quickly than by chemical methods, and it would appear that since the possible sources of error are less numerous the result should be more dependable. Research in the mechanisms of lead poisoning will be aided by the development of this analytic method which is applicable not only to the blood and other fluids but to the solid tissues of the body as well. Its use as an aid in the clinical diagnosis of lead poisoning will no doubt rapidly become general.

REVIEWS

A Diabetic Manual By ELLIOTT P JOSLIN Fifth Edition 224 pages, 14 × 20.5 cm Lea and Febiger, Philadelphia 1934 Price, \$2.00

This small volume is so widely known to the profession as to need only brief review. To those who have not employed it in their practice it may be highly recommended, especially for intelligent patients. It is written so as to present to the patient, and incidentally to his physician, the more important facts concerning diabetes: the factors predisposing to it, its symptoms, course, complications, prognosis, relationship to marriage and pregnancy, and the various aspects of its treatment by diet and insulin.

However, it is not only facts that Dr. Joslin presents, but a religion for the diabetic. To adhere rigorously to treatment in order to live longer is shown to be the diabetic's duty not only to himself but to other diabetics who will be encouraged to do likewise. The author's enthusiasm leads him into a peculiarly personal method of presentation. He pleads the cause of optimism for the diabetic and goes at some length into the statistical basis for optimism. Pictures of vigorous youngsters with diabetes are freely used. Short case histories are presented to illustrate the results both of good treatment and neglect of treatment. There is no other manual for diabetics which does so much to develop the morale of the patient.

Some Modern Extensions of Beaumont's Studies on Alexis St. Martin Beaumont Foundation Lectures. Reprinted from the *Journal of the Michigan State Medical Society*, March to May, 1933. By W. B. CANNON, M.D., S.D., LL.D., George Higginson Professor of Physiology, Harvard Medical School. 87 pages, 13.5 × 20.5 cm. Wayne County Medical Society, 4421 Woodward at Canfield Detroit 1933.

The Twelfth Series of Beaumont Foundation Lectures commemorated the one hundredth anniversary of the publication of William Beaumont's classic "Experiments and Observations on the Gastric Juice and the Physiology of Digestion." As lecturer, Dr. Cannon chose to compare modern knowledge of certain phases of digestive physiology with Beaumont's observations in these same fields. The three lectures deal with "Thirst and Hunger," "The Important Relations of Digestion and Health," and "Digestive Disturbances Produced by Pain and Emotional Excitement." They constitute interesting and clearly presented accounts of advances in these fields but are not complete surveys of present knowledge, and do not present any new concepts.

M C P

Practical Methods in Biochemistry By F. C. KOCH, Professor of Physiological Chemistry, University of Chicago, vii + 282 pages, 16 × 23.5 cm. William Wood and Co., Baltimore 1934. Price, \$2.25.

For some time physiological chemistry departments have found it necessary to formulate manuals of their own for all laboratory work, which involved considerable time and expense. This laboratory manual should fill this deplorable want for such books. Although the author has intended this as the "practical companion" of Professor A. P. Mathews' textbook, it can be used with ease with any text desired.

The manual is arranged in three parts: the chemistry of cell constituents, the chemistry of the digestive tract and blood and urine. These are in turn divided into

chapters dealing with individual subjects. The experiments are preceded by brief discussions of the chemistry involved, including references to the original articles. Dr Koch has not been sparing in the number of experiments presented, so that it is possible to make a choice of those that seem more pertinent for the particular course offered.

The manual is modern in every sense of the word, for the author has rejected in some parts old and customary experiments for those that have but lately been presented in the journals. This is rather markedly illustrated by the introduction of methods for quantitative glucose determinations in the urine other than the standard Benedict's quantitative test. For the most part, however, the old methods, with improvements if possible, are included along with the newer ones.

The appendix is complete with instructions to the student as to laboratory procedures and technic, with discussions as to normal and molar solutions and with methods for preparing all solutions.

Finally, it is a splendid book of its kind, up to date in its material and complete in its discussions and directions.

E M R

Recent Advances in Pathology By GEOFFREY HADFIELD, M D, F R C P (Lond), and LAWRENCE P. GARROD, M A, M D, B Ch (Camb), M R C P (Lond)
xii + 457 pages, 15 × 21 cm P. Blakiston's Son and Co, Philadelphia 1934
Price, \$4.00

The second edition of this excellent little book has been issued within two years of the first. It contains a number of additions, notably an elaboration of the authors' reasons for looking upon the major forms of anemia as primarily due to disorders of gastrointestinal function.

It is evident that judgment as to the relative importance of advances in a field as broad as that of pathology is bound to be an individual matter. The authors have made a very catholic selection of topics for discussion, grouping them partly under the systems of the body, and partly under such general headings as the reticulo-endothelial system, the deficiency diseases, the ductless glands, etc.

The discussion of the recent advances in our knowledge of cancer constitutes a valuable summary of this subject divided into chapters on carcinogenesis by irritants, the transplantation of tumors, tumor metabolism, heredity, and therapeutic cancer research. The authors have a gift of clarity of style and of concise statement, which enables them to present the complex and confusing data in this field in a clear and highly interesting way. The critical analysis of the experimental evidence adds a great deal to the value of this section. The treatment of other topics is much briefer than that devoted to the cancer problem, and though most of the sections are adequate and stimulating certain of them suffer from too great condensation. This seems true, for example, of the discussion of anoxemia which will probably seem clear only to those who are already reasonably acquainted with the subject. The statement made on page 241 that "the respiratory center responds not to a reduction of oxygen in the circulating blood but only to an increase of CO₂," is misleading. The discussion of recent work on pneumonia is even more inadequate. The types of pneumococcus are considered, but the discovery of the specific capsular polysaccharides and Avery's work on the enzyme destruction of the Type III polysaccharide are not mentioned.

The task as a whole, however, is well performed, a very clear and critical summary of many of the chief advances in the field of pathology is presented in brief form. It is a book worthy of repeated editions. The illustrations are excellent, the references well chosen. Internists will find it readable, instructive and stimulating.

M C P

The Dangerous Age in Men A Treatise on the Prostate Gland By CHESTER TILTON STONE, M D 105 pages, 14 X 20 cm The MacMillan Company, New York City 1934 Price, \$1 75

In the reviewer's opinion this book should not have been published by a reputable firm. It is the type of pseudo-scientific description of the relation of the sexual glands to sex life and to health in general that is particularly apt unnecessarily to alarm the layman for whom it is intended. According to the author, the disorders and diseases of the prostate are, with few exceptions, the commonest affecting adult males, but "by properly caring for this organ, the entire body becomes like a car brought up to date." He feels that it is safe to say that 60 per cent of all men past 40 have trouble with the prostate gland and "deferring old age resolves itself either into keeping these glands fit or into bringing them back to their proper function." "Since without sexual power there can be no real bodily and mental strength or capacity this power must be kept in a state of efficiency by the regular and proper exercise of the sexual functions." On page 51 a case is cited to support this need of intercourse. A widower develops prostatic symptoms and is advised to remarry. Failing compliance in this or in medical treatment it is stated that "the prostate would have gone on swelling until finally a tumor of the prostate developed."

The several chapters on the horrors of prostatitis, seminal vesiculitis, etc., are not only full of exaggerated and incorrect statements, but are calculated to give to laymen an entirely false idea about the efficacy of local treatment of the prostate. The book as a whole constitutes an abuse of the physician's privilege of advising the public.

M C P

Medicine, a Voyage of Discovery By JOSEF LOBEL, translated from the German by L. MARIE SIEVEKING and IAN D. MORROW 334 pages, 15.5 X 22 cm Farrar and Rinehart, Murray Hill, New York 1934 Price, \$3 00

Here are 16 essays telling the story of medicine in a somewhat different way from that ordinarily used. The first and last articles are on medicine and the others take up biology, anatomy and the other branches of the healing science and art. It is a book written by a man of wide learning and true culture who appreciates how medicine came into being and what it really is all about. The book is well translated and conveys the charm which must characterize the original. There is a slip by the translators who use the word typhus where they should have employed typhoid but it is a natural one considering the term as it is used in German.

The author does not give the earlier physicians their due. He fails to mention Minot in connection with the account of pernicious anemia, contenting himself with setting it down as an American contribution. There are a few other omissions of the same nature. He spells the anatomist Monro's name with an *e* added and leaves one a little confused as to where the resurrectionist scandal took place. These are in themselves small matters, for the book is a fine one, suited for medical men and particularly for medical students and nurses, to say nothing of the well educated layman. It will make a most acceptable Christmas present.

J R

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following donations by members to the Library of the College by the authors

Dr R Manning Clarke (Fellow), Los Angeles, Calif —1 book, "Diseases of the Heart"

Major J R Darnall (Fellow), Ancon, C Z —2 reprints

Dr Ralph W Mendelson (Fellow), Albuquerque, N M —1 reprint

Dr Oscar W Bethea (Fellow), professor of therapeutics, Graduate School of Medicine, Tulane University, New Orleans, La, delivered the commencement address at the one hundred and twelfth annual commencement of the Philadelphia College of Pharmacy and Science during June. He was the recipient of the honorary degree of Master of Pharmacy from the College, as was also Dr Walter Bastedo (Fellow) of New York City

Dr Edgar Erskine Hume (Fellow), Major (M C), U S Army, was the recipient of the honorary degree of Doctor of Laws at the last annual commencement of Georgetown University

Dr David P Barr (Fellow), St Louis, Mo, has been giving a course of lectures on diseases of the endocrine glands at the University of Melbourne, Australia, during the past summer

Dr Frederick H Lamb (Associate), Davenport, Iowa, is the newly installed president of the American Society of Clinical Pathologists

Dr Kennon Henry Dunham (Fellow), Cincinnati, Ohio, is the newly elected president of the National Tuberculosis Association

Dr James P Leake (Fellow), senior surgeon, U S Public Health Service, has been relieved from duty in the division of sanitary reports and statistics and assigned to duty in the division of scientific research, effective June 23. He is in California cooperating with health officials in combatting the recent outbreak of poliomyelitis

Dr Frederick K Herpel (Fellow), West Palm Beach, Fla, is the newly elected president of the Florida Radiological Association

Dr Howard T Karsner (Fellow), Director of the Institute of Pathology of Western Reserve University, Cleveland, Ohio, will attend the triennial conference in Europe of the International Society for Geographic Pathology, meeting in Utrecht, Holland, of which he is a member of the Directorial Committee of five members. Later he will visit laboratories in London and Cambridge, England, Hamburg and Freiburg, Germany, and Strasbourg, France

Dr William H Walsh (Fellow), hospital consultant, of Chicago, sailed July 21 for Leningrad, where he will make an independent study of health and hospital conditions and practices in the U S S R. Dr Walsh's itinerary will take him to Leningrad, Moscow, Kharkov, Odessa, Kiev and Minsk, returning in September via Warsaw, Berlin and Paris

Dr B S Pollak (Fellow), Medical Director of the Hudson County Tuberculosis Hospital and Sanatorium, Secaucus, N J, has announced the initial work on the construction of a new 25-story tuberculosis hospital

Dr Grafton Tyler Brown (Fellow), Washington, D C, was recently elected president of the Georgetown Clinical Society

Dr Alexander B Moore (Fellow), Professor of Roentgenology at the Georgetown University School of Medicine, Washington, D C, delivered the Russell D Carman Memorial Lecture on "Function of the Roentgenologist in the Diagnosis of Intra-Abdominal Conditions" at the eighty-first annual session of the Minnesota State Medical Association held in Duluth, July 15 to 18

Dr Willard Cole Rappleye (Fellow), Dean of Columbia University College of Physicians and Surgeons, has been appointed Dean also of the School of Dental and Oral Surgery, beginning July 1

Dr Bailey K Ashford (Fellow), retired Colonel of the Medical Corps of the U S Army, has just published an autobiography, "A Soldier in Science" A dinner in honor of Dr Ashford was held at the Harvard Club, June 27, sponsored by New York physicians and officials of the Pan American Medical Association, in recognition of his contributions to tropical medicine

Dr Hillyer Rudisill, Jr (Fellow) has been made Professor of Roentgenology in the Medical College of South Carolina

The National Research Council has announced the following grants in the field of medical sciences to Fellows of the American College of Physicians

Dr John A E Eyster, Professor of Physiology, University of Wisconsin Medical School, the electrical field around the contracting heart and skeletal muscle and related phenomena

Dr Frank A McJunkin, Professor and Head of the Department of Pathology, Bacteriology and Preventive Medicine, Loyola University School of Medicine, Chicago, extraction and purification of agents that inhibit mitotic proliferation in the kidney

Dr Edward B Krumbhaar (Fellow), Philadelphia, was elected President of the American Association of the History of Medicine at its last annual meeting in Cleveland, June 11

Dr William S Middleton (Fellow), Madison, Wis, was elected a Vice-President, and Dr E J G Beardsley (Fellow), Philadelphia, Secretary

Dr Alfred Friedlander (Fellow), Professor of Medicine, University of Cincinnati College of Medicine, has been appointed Dean of the College to succeed Dr Arthur C Bachmeyer, resigned Dr Friedlander will assume office September 15

ACUTE MONOCYTIC LEUKEMIA

THE PROBLEM OF MIXED LEUKEMIA

ETIOLOGIC CONSIDERATIONS

DISCUSSION

SUMMARY

MODERN cytologic, physiologic and pathologic studies have left little doubt as to the separate identity and functional independence of the monocyte of the blood and connective tissues. Adequate criteria in fixed as well as supravital technics are now available for sharply differentiating this strain of cells from the other leukocytic elements in the circulating blood, and important new diagnostic and prognostic interpretations of great significance are attaching to the data rapidly accumulating from the newer blood studies in such conditions as tuberculosis,¹⁻⁶ pneumonia,⁷ Hodgkin's disease⁸ and syphilis,⁹ to mention only the more outstanding examples.

THE MONOCYTE AND THE CELLS OF THE BLOOD

The history of the changing conceptions, which have from time to time been held concerning the monocyte, follows closely the development of new technics, each bringing its additional clarifying criteria of physiologic or morphologic significance to the problem. The monocyte was first considered in the original Ehrlich classification as a transitional form in the maturation of the neutrophilic leukocyte. Naegeli concurred in this view. With the introduction of the Romanowsky methylene blue-azur staining

* Read in part before the American College of Physicians, Chicago, Ill., April 17, 1934.
From the Department of Medical and Surgical Research, Ohio State University.

technic, Michaelis and Wolfe¹⁰ (1902) observed that monocyte and lymphocyte both contained azur granules, the neutrophils having quite different specific granular bodies, and Pappenheim and Ferrata¹¹ conclusively demonstrated in 1911 the independence of blood monocyte and granulocyte. The fact that monocytes are found only under pathologic conditions in the bone marrow¹² but may be found regularly arising in the spleen¹³ and peripheral lymph nodes,¹⁴ further tended to link monocyte and lymphocyte, and the evidence of tissue culture¹⁵ has been interpreted in support of a genetic relationship between these two cell strains. The azur granules, however, of the lymphocyte are relatively large, few in number, and inconstant in a clear cytoplasm, while the azurophilic granules of the human monocyte are tiny, usually extremely numerous, and imbedded in a dense, opaque, moderately deeply basophilic background. Schilling-Torgau,¹⁶ carefully analyzing these differential morphologic criteria, in 1912 definitely described the monocyte as making a third strain of the white cells, distinct on the one hand from lymphocytes and on the other from granulocytes, and thereby became the first hematologist prepared to recognize any dyscrasia specifically involving the monocyte. It is not surprising, therefore, that the very next year, 1913, Schilling-Torgau with Reschad¹⁷ should have discovered and reported the first case of monocytic leukemia. The more recent studies of the monocyte by Sabin and her coworkers² and of the lymphocyte by Wiseman¹⁸ have produced a new wealth of evidence substantiating the independence of each of these cell strains and their frequent reciprocal relationship to each other in various pathologic states.

THE MONOCYTE AND THE CELLS OF THE CONNECTIVE TISSUES

There still exists, however, a widespread skepticism as to the existence of a leukemic state involving primarily and solely this so-called monocyte of the blood and its anlagen in the connective tissues. This is explainable perhaps upon two grounds: first, a continuing inability on the part of the average physician and laboratory technician to identify and sharply differentiate in ordinary blood films this distinctive cell type, and second, a confusion relative to nomenclature, functional specificity, and morphologic differentiation of the cells of the connective tissues which is quite as profound and widespread as that involving the cells of the blood. Ranvier¹⁹ in 1891 described the powers of phagocytosis exhibited by certain free connective tissue cells which he termed "clasmatocytes." Metchnikoff²⁰ (1883-1892) then differentiated the circulating ameboid phagocytic polymorphonuclear cells of the blood, "microphages," from the relatively less ameboid phagocytic "macrophages" of the tissues, including among the latter the stellate cells of Kupffer in the liver, certain endothelial cells and the large mononuclear cells of the tissues, splenic pulp and lymph nodes. Marchand²¹ demonstrated the derivation of clasmatocytes from mesenchymal elements more especially those found in the adventitial sheath of

blood vessels, and showed that in inflammation these adventitial cells were transformed into the macrophages of Metchnikoff Maximaw²² (1902) also studied the mononuclear ameboid phagocytes in inflammatory tissues calling them "polyblasts" Ribbert²³ (1904) then found that cells of this group picked up colloidal suspensions of various composition, as for example sugar of iron, and that they segregated non-toxic dyes such as lithium carmine when the latter were introduced into the blood stream This intravital reaction was quite specific in that general vascular endothelium and fibroblasts took a negligible part in the phagocytic phenomenon, and muscle fibers rejected these vital dyes entirely Goldmann²⁴ and his associates followed with a study of the cells reacting to pyrrhol blue, demonstrating the identity of Ranvier's clasmotocytes with Marchand's adventitial cells and Maximaw's polyblasts In 1913 Aschoff and Kiyono²⁵ introduced the term "histiocyte" to designate this mesenchymal mononuclear phagocyte of the connective tissues and popularized the reticulo-endothelial concept based upon the observed degree of intensity and frequency of phagocytosis by this specific group of cells in the connective tissues

This was the general situation when interest became aroused in a new range of criteria for differentiating the mononuclear cells of the blood afforded by the application of neutral red and Janus green to living cells through a supravital technic While practically the whole experience with tissue culture^{26, 27} up to the present time has tended to strengthen the position that monocyte of blood and clasmotocyte of tissue are but different phases in the life cycle of one strain of cells,—the connective tissue macrophage,—both supravital-morphologic and clinical-pathologic studies have been accumulating which provide pertinent data raising at least a reasonable doubt as to the validity of this conclusion When the living cells are studied supravitaly, the monocyte, whether in the blood or in the tissues, reacts to the neutral red with a rosette of small vacuoles staining a characteristic uniform salmon pink and arranged more or less symmetrically in a concentric halo about the centrosphere in the hof of the nucleus Dark field examination of fresh unstained blood films confirms this pattern as indigenous to the normal living cells and not an artefact or the result of a toxic reaction to the dyes Neither lymphocyte, granulocyte nor clasmotocyte contains such a pattern of vacuoles, either in the presence or absence of the dyes mentioned, and the pH of the intravacuolar fluid in the monocyte as revealed by the indicator neutral red (pH 6.8–8.0) is so constant as to give a uniform tinctorial reaction which characterizes the monocyte throughout the animal kingdom These structures so readily demonstrated in the living monocyte are not identical with the azurophilic granules revealed in the fixed films stained with the Romanowsky dyes Furthermore, a careful quantitative survey of peroxidase stained films usually rewards the discriminating searcher with definite differences in the degree and distribution of oxidase granules in the monocytes as contrasted with granulocytes,²⁸ the

lymphocytes always, of course, being oxidase negative. The first specific vacuoles appear, as do the granules of the myelocyte, in a primitive basophilic cell, the *monoblast*, which passes through a developmental period consisting in the gradual elaboration of these structures before functional maturity and motility appear.²⁰ Unlike the definitive granulocytes and erythrocytes, the monocyte of the circulation continues to show numerous mitochondria and retains the power of mitosis, division figures being encountered not infrequently in the blood stream under relatively normal conditions. The clasmatoocyte, in contradistinction, is seldom seen in the peripheral circulation in health.³⁰ It is usually a larger cell without apparent maturation cycle, with no cytoplasmic pattern, more highly phagocytic than the monocyte for larger bodies, such as whole red and white cells, and with segregation vacuoles reacting to neutral red in a range from yellow to deep maroon, i.e., over the entire pH indicator range of neutral red. In brief, the supravital studies of Sabin, Doan and Cunningham^{2, 31} have resulted in data which help to clarify the issues thus far discussed in three directions: (1) the rosette of vacuoles reacting to neutral red in the living monocyte, when taken in combination with other distinctive morphologic criteria, sharply differentiates this cell from each of the other types of blood and tissue cells, thus supporting and confirming the previous evidence upon which its separate identity has rested, (2) the monocyte of the blood is identical with the monocyte of the tissues and reflects directly and quantitatively the proliferative activity of these elements in the body as a whole, (3) the mononuclear phagocytes of the tissues making up the so-called reticulo-endothelial system, are of two morphologic, functional and probably genetically distinct strains, the one (the monocyte) a derivative of mesenchymal reticular tissue, the other (the clasmatoocyte) an endothelial derivative, of Kupffer cell and splenic macrophage type. While no unanimity of opinion as to its exact life history has as yet been reached, as was emphasized recently by Forkner,³² who listed no less than 19 separate views as to the origin of the monocyte, it is our belief that the clinico-pathologic evidence beginning to accumulate upon the basis of the now adequate morphologic criteria essential to the recognition and differentiation of this cell, already bids fair to confirm more conclusively a mesenchymal connective tissue anlagen for the monocyte identical with or closely similar to that from which the lymphoblast and myeloblast arise. The balance of specific differentiating stimuli at any given time or location must determine the character of the definitive cell type to be produced.

Thus, the monocyte, threatened repeatedly with incorporation into the life cycle of one or other of the firmly established strains of the white cells, and surviving this fate only to have its birthright threatened once again in the discussion as to the oneness of all mononuclear phagocytes in the tissues, has survived successfully nevertheless, these histological and physiological controversies of recent years.

THE MONOCYTE IN PATHOLOGIC STATES

Perhaps the most extensive and complete studies of the monocyte in disease have been those initiated by Sabin and her associates^{1,2} in the analysis of the cellular reactions in tuberculosis. The epithelioid cell of the tubercle has been proved to be but an altered phase in the life cycle of the monocyte. Except in caseous foci the tubercle bacilli are found almost exclusively within the epithelioid cells, apparently in symbiotic interrelationship,—a manifestation of the phagocytic receptiveness of this mononuclear cell. In experimental tuberculous disease, prior to the appearance of any increase in mature monocytes in the blood or of epithelioid cells in the tissues, a marked hyperplasia of primitive blast cells occurs at the point of lodgment of acid fast organisms.²⁹ These have been proved to be monoblasts by the subsequent observance of their speedy maturation into typical monocytes and epithelioid cells within which the tubercle bacilli are thereafter usually found. Coincident with, and not prior to, the increase of these cells in organs and tissues there appears an increase in their representation in the circulating blood. Consequently, an absolute monocytosis in the blood in tuberculosis indicates the progressive formation of new tubercles in the tissues. When taken in conjunction with the qualitative as well as the quantitative data now determinable for granulocytes^{33,34} and lymphocytes^{18,35} a valuable source of information about any given tuberculous patient is at once available.

The biological studies, however, of the chemical fractions from the acid fast bacteria have laid the foundation for the most promising conception of the nature of the fundamental stimuli responsible for monocytic proliferation. A thorough survey extending through the past decade with adequately prepared and controlled chemical fractions³⁶ has established conclusively the fact that the lipoids, more particularly the tuberculo-phosphatides, are solely responsible for the monocyte-epithelioid proliferation and differentiation in tuberculosis, and that the ultimate active principle is to be found in one or more of the newly isolated fatty acids from this material.²

It is of interest in this connection to note that a similar response to lipoids has not been observed for the clasmatocytic elements of the connective tissues. In experimental kala azar,³⁷ however, there appears to be as specific host-parasite relationship between clasmatocyte and the *Leishmania donovani* bodies as in tuberculosis between monocyte and tubercle bacilli. A sharper pathologic differentiation of these two cell types is thus exemplified in the tissue reactions of these two diseases than exists physiologically, which suggests different inherent cell-strain capacities for phagocytic response.

Other conspicuous examples of the monocytic reaction to bacterial invasion are provided in syphilis,⁹ typhoid fever,³⁸ undulant fever,³⁹ and in *B. monocyto genes* infection of rabbits.⁴⁰ In lobar pneumonia, Hickling⁷

has demonstrated a transitory reflection in the blood of an increased mobilization of monocytes in the lung during the period of resolution, the monocytosis being indefinitely maintained if empyemic complications arise. Under these circumstances the demand for an increased phagocytic function is apparent and prognostic data are accordingly enhanced when the monocyte factor is recognized.

THE MONOCYTE IN LEUKEMIA

During the latter part of the last century it was currently believed that all acute leukemias were of lymphoid origin. Fraenkel⁴¹ in 1895, among others, emphasized the lack of differentiating criteria, which marked the cells of the majority of such syndromes as lymphocytic elements. With the recognition and separation of the myeloblast on morphologic grounds by Naegeli⁴² in 1900, it became gradually apparent that many of the cases which upon superficial examination revealed a predominance of cells without the usual complement of specific granules in the cytoplasm, nevertheless represented disturbances in myelopoiesis so profound as to permit the delivery into the active circulation of greater or lesser numbers of these agranular, myeloblastic elements, usually restricted to the marrow.^{43 44, 45} The elaboration of new technics for the accentuation of the differences, which become less and less distinctive and characteristic of the respective cell strains the earlier the individual units are seen in their respective maturation cycles, has made for continued progress in the differential diagnosis of this group of leukemic dyscrasias. Schilling's comparable contribution (1912) toward the separate identity of the monocyte, laid the foundation for the recognition of the third type of leukemia, but despite Schilling's pioneer observations made more than two decades ago, a leukemia in which the monocyte seems to be primarily involved is only just beginning to be recognized sufficiently widely and frequently to furnish the basis for clinicopathologic studies leading toward the revelation of further details about this strain of cells. As may be seen from the accompanying diagram, the monocyte satisfies all of the theoretic demands necessary for the development and appearance of pathologic states parallel to and characterized by the same varying symptomatology as those involving the longer established cell strains. If the medical literature on this subject may be subjected to interpretation at all, it reveals the protean manifestation of clinical signs and symptoms which has obtained in the cases reported as suffering from monocytic leukemia. A personal experience during the past four years with some 75 cases of leukemia (table 1) of all types and degrees of severity

TABLE I

| | |
|--|--------|
| The Leukemias of All Types Studied during a Four Year Period | |
| Total Cases 1930-34 | 76 |
| Myeloid Leukemia | 28-37% |
| Lymphatic Leukemia | 36-47% |
| Monocytic Leukemia | 12-16% |

and manifesting widely divergent cellular reactions has made the present authors keenly aware that the only basis upon which ultimate differentiation of the several types can be accurately and consistently made is that which rests upon the morphologic and behavior characteristics of the circulating cells themselves as they appear under the conditions provided by supravital as well as fixed staining technics. There is no clinical syndrome in our experience which is pathognomonic of monocytic leukemia as distinct from myeloid or lymphatic leukemia. Certain generalizations have been attempted by some authors but these have been made largely from analyses of the literature since no single investigator has as yet had a personal experience great enough to draw upon statistically, and it is our opinion that up to the present moment the difficulties inherent in the differentiation and identification of lymphoblast, myeloblast and monoblast, to say nothing of more mature monocytes and myelocytes "B," have been sufficiently great to render it worse than useless to attempt to judge from "the published records" the principle underlying cellular pathology in any given case. And this is not to doubt the authenticity and existence of many more cases of monocytic leukemia than have begun to be reported. Dameshek,⁴⁶ reviewing the literature up to and including 1929, was inclined to accept 18 of the 31 then reported cases. Clough⁴⁷ in a further analysis (1932) endorsed as true instances of monocytic leukemia 22 of the then accrued 39 cases. Up to and including the early part of this year, 1934, we have found some 75 reported cases exclusive of those designated as aleukemic reticulo-endotheliosis, many of the latter doubtless belonging in this general group. Because of the reasons cited, we prefer not to attempt a critical evaluation of the individual cases. Ultimately the registry for thoroughly studied and authenticated cases of monocytic leukemia which the Clinical Pathologists have organized under Dr. Kracke's direction, will furnish the proper basis for such an appraisal and statistical analysis.

Our own experience confirms the general impression conveyed by the literature that every feature common to myeloid and lymphatic leukemia has been found in the monocytic form. Thus, monocytic leukemia has been reported as occurring at any age from 11 months⁴⁸ to 71 years⁴⁹, and it may be relatively chronic,⁵⁰⁻⁵¹⁻⁵² subacute⁵³⁻⁵⁶ or fulminant^{32, 50, 57-59, 64, 65} or it may, with leukemic or aleukemic blood, present a confusing picture of the so-called mixed leukemia type, it may be associated with a neoplastic growth⁴⁶ similar in all respects to leukosarcoma⁶², it has shown the skin manifestations of leukemia cutis⁶⁰⁻⁶³. Cases without demonstrable splenomegaly,⁴⁷⁻⁴⁹⁻⁵⁷⁻⁵⁹ lymphadenopathy⁴⁷⁻⁵⁰⁻⁶⁴ or without hemorrhagic manifestations are described⁵²⁻⁵⁷⁻⁶⁶. One or other of these variations has been reported from single case studies by individual investigators usually, but it has been possible for us to observe all of these respective clinical manifestations in the present series of nine personally studied and verified cases of the disease, and to make the diagnosis in three other patients from whom blood films have been available for confirmation of the cell type involved.

During the same period we have seen from the same general cross section of patients 28 myeloid and 36 lymphatic leukemias. Our experience would thus suggest an incidence of monocytic leukemia of 16 per cent or less, with approximately 37 per cent myeloid and 47 per cent lymphoid leukemias on the basis of 76 cases studied over a four year period. The age incidence in our series has been from four to 70 years, seven were male, five female patients, the known duration of the disease was from six weeks to four years.

CHRONIC MONOCYTIC LEUKEMIA

The verification of the existence of a relatively benign, chronic state of monocytic leukosis is essential to the full establishment of this leukocytic element on a pathologic par with granulocyte and lymphocyte. A true chronicity, however, has seldom been encountered or recognized in the leukemias of monocytic type, as judged by a survey of the literature to date, though a chronic or subacute syndrome is perhaps more commonly seen than the very acute process in the leukemias of myeloid and lymphatic origin. It happens that the first case recognized by us as coming under the general category of monocytic leukemia was encountered within the first two months of the establishment of our blood clinic at Ohio State University in the fall of 1930, and represented an extremely chronic, non-progressive syndrome, the patient eventually succumbing to cerebral hemorrhage after a year's observations without an acute exacerbation of the leukemic process at any time.

CASE I

J. G., white, male, aged 66 years, a retired hardware salesman, was first seen September 12, 1930, at the request of Dr. L. H. vanBuskirk. Following the extraction of 12 upper teeth January 28, 1930, there had been profuse hemorrhage persisting for 24 hours to the point of serious exsanguination, the patient fainting upon the least exertion. For several months thereafter he remained excessively weak and finally returned to his physician early in September saying he had been unable to regain his accustomed vigor since the experience of the preceding January. About 15 pounds in weight had been lost. A moderate hypertension (162/100) existed. The remaining teeth showed extensive caries. Heart and lungs were reported as essentially negative. The urine showed a trace of albumin and a few casts, no pus. The blood examination showed erythrocytes 3,690,000, hemoglobin 60 per cent, leukocytes 12,480, and the differential count revealed PMN 33 per cent, PME 3 per cent, myelocytes 7 per cent, lymphocytes 21 per cent, monocytes 36 per cent. An elimination of obvious toxic foci in the mouth was advised and the remaining teeth were promptly extracted. No immediate difficulty ensued but one week following the extractions a severe hemorrhage occurred from the tooth sockets persisting for 24 hours and requiring the services of a physician to control. It was at this point that consultation was requested and we had the opportunity of following personally the subsequent course of events. Our first complete studies October 16, 1930, revealed 4,250,000 red cells with hemoglobin of only 67 gm. in 100 c.c. blood, 60,000 platelets and 26,900 leukocytes with the following supravital differential: active PMN 16.5 per cent, round 2 per cent, vacuolated 0.5 per cent, non-motile 1 per cent, baso-

philes 0.5 per cent, eosinophiles 1 per cent, myelocytes "C" 1.5 per cent, small lymphocytes 10 per cent, intermediate 1 per cent, large lymphocytes 0, monocytes, active 65 per cent, clasmatoocytes 0.5 per cent, unclassified 0.5 per cent, hematocrit 31.5, average diameter erythrocytes 7.64 microns, sedimentation 25 mm in 1 hour, icterus index 9, erythrocyte fragility 0.520-0.340

On October 20, 1930 the patient was admitted to the Research Service, University Hospital, for a five day period of observation. Except for the dental condition and a moderate hypertension the patient had been in good general health prior to January 1930. In early childhood he was subject to chills and fever, presumably malaria for they were controlled with quinine. At 11 years and again at 20 he had pneumonia with, in each instance, a prolonged convalescence of 10 to 12 weeks. During seven years, between the ages of 54 and 61, recurrent attacks of jaundice associated with pain in the region of the gall-bladder were experienced. Other than on the two occasions previously mentioned no history of hemorrhages, epistaxis, or purpura was obtainable. The family history was entirely negative in so far as it might relate to the patient's present illness.

Physical examination on first admission to Hospital T 98° F, P 70, R 18. Blood-pressure, 170 systolic and 100 diastolic. Weight 138 pounds. There was a marked pallor. Nodes in the anterior cervical chain of the right side, 1 cm in diameter, were palpable with none demonstrable on the left. The posterior cervical, submaxillary, submental and epitrochlear nodes were not palpable. In the left axilla two to three small nodes 1 cm in diameter were felt but none were found on the right. A few small inguinal nodes were present. The palpable nodes were discrete, movable, elastic, not tender. The chest was negative except for a moderate degree of cardiac enlargement. The liver could be felt 4 cm below the right costal margin, the spleen was not palpable. Reflexes not remarkable.

Laboratory Studies The cytological studies of the blood may be followed on chart 1. Gall-bladder visualization was successful, no evidence of calculi was found and there was rapid emptying following the fat meal. The humerus, radius, femur and tibia on the right side showed no radiologic evidence of any pathologic process, a marked density of the bones of the skull was apparent. Blood chemistry NPN 28, urea nitrogen 11.4, urea clearance 46.2. Blood culture, negative. The basal metabolic rate was plus five and plus ten on two days. Tuberculin Mantoux tests (human, bovine and avian) were all negative. Urinalyses showed granular casts (two plus), and albumin 25 mg. Phosphatid precipitin test, antigen A-3 H-37, positive 1-1280. An exploratory biopsy failed to yield the desired lymphatic tissue for histologic study.

In brief, the hospital study failed to reveal any apparent cause for the abnormal differential blood count, but confirmed beyond any reasonable doubt the monocytic character of the established mononuclear predominance in the circulation of this patient. A three hour study with observations taken at 15 minute intervals in order to appraise the rhythmic cycle of the different cellular elements showed a disordered mechanism for the monocytes, which together with the shift to the left with a dominance of quite young forms among this group, served to establish the diagnosis of chronic monocytic leukemia. The relative but not absolute decrease in granulocytes and lymphocytes with their more moderate "shift to the left" and relatively unaffected normal rhythm suggests a secondary rather than a primary participation of these elements in the syndrome.

Little change was noted during the succeeding months except that the hemoglobin increased to 12 gm per 100 cc of blood by January 1931 and the platelets increased to between 130,000 and 350,000 with no hemorrhagic tendencies manifest. Desired activities were not denied the patient, and he enjoyed a relatively normal life. The total white count ranged between 15,000 and 30,000, with the monocytes representing from 11,000 to 22,000 cells.

CHART 1 This patient showed a persistent monocytic elevation largely responsible for the increase in total leukocyte count, but without significant clinical symptoms of leukemia, during the year of observation. The lymphocytes were unchanged either in quality or quantity. Myelocytes were consistently present, fluctuating between 200 and 2,000 per cu mm. During the period of arsenic medication the myelocytes were reduced as well as the mature granulocytes, but on the rebound following the stopping of the medicine they rose to a high point of 9,000 per cu mm. Following the cerebral hemorrhage the terminal blood picture showed 14,000 mature granulocytes, 11,000 myelocytes, 7,000 lymphocytes and 60,000 monocytes. (See plate 3, figures 1 and 6, for the type of monocyte involved.)

With the hope of increasing the reserve of the patient's strength by attempting to establish the white count on a lower level with a more nearly normal differential, it was decided in July 1931 to institute arsenic therapy in the form of Fowler's solution. As is usual when this treatment is used in myeloid leukemia a definite increase in total count was noted during the first ten days of medication up to 42,000, the increase being specifically due to a relative and absolute increase of monocytes, from 60 per cent to 80 per cent of all cells, or from 14,000 to 34,000. Granulocytes and lymphocytes were essentially unaltered except that the granulocytes were decreased during the period of lowest total white counts (8,000) at the end of the period of medication. Starting with five drops three times a day the dose was gradually increased until the white count had been reduced to 20,650 by the end of the seventeenth day with a maximum dosage of 33 drops per day. Definite toxic symptoms appeared at this time. The medication was immediately stopped, and within the following 48 hours all acute symptoms had passed. The total white count at this time was 13,850. Three days later the white count reached its lowest level of 8,350, with 23 per cent neutrophils, 1 basophile, 1 myelocyte, 22 per cent lymphocytes and 53 per cent monocytes. A rapid rebound in the total count and its constituent elements, more particularly the monocytes and myelocytes, carried the cells to a new high of 68,000 per cu mm during the ensuing two weeks with a return to the premedication equilibrium one week later.

During August and September the patient was in unusually good health and spirits. On September 26 he was suddenly seized with generalized convulsions in his home. The patient was immediately transferred to the Hospital where the convulsive seizures were readily controlled with luminal sodium. The white count on admission was 90,000 with 68 per cent very young monocytes (Plate 3, figure 1). The patient died in coma at 7:30 the following morning.

Postmortem examination was made by Dr Ernest Scott, late Pathologist to the University Hospital, at 11:30 a.m. Nothing remarkable on external examination, no generalized adenopathy. The peritoneal lining was smooth and glistening. The liver was at the costal margin, normal in size and appearance except for some slight thickening of the capsule in places, with no gall-bladder lesion. The spleen measured 15 by 9 by 4 cm and weighed 260 grams, it was brick red in color, firm with some mottling of the cut surface and an absence of follicles. The stomach, the small and large intestines, the pancreas, both adrenals and the prostate gland were normal to gross examination. The kidneys were normal in size, the capsules were adherent and there were cortical cysts measuring as much as 1.5 cm in diameter, each kidney presented a dilated pelvis and thinned out cortex, both ureters were normal, the urinary bladder was normal. The pleural cavities were free of adhesions and showed no increased fluid. The lungs were air containing throughout, the vessels and bronchi at the hilus were normal, an old scar was found at the right apex but no evidence of tuberculosis was present. The hilus lymph nodes were

FIG 2 Case I Chronic monocytic leukemia. Photomicrograph of the femoral bone marrow showing the hyperplasia of monocytic elements with typical nuclear characteristics. Oil immersion, $\times 960$ H and E.

FIG 3 Case VIII Acute monocytic leukemia. Foci of monocytic cells scattered throughout the liver, more frequently periportal in location. Low power $\times 100$.

FIG 4 Case VIII A higher power of the liver of figure 3, showing the character of the cellular proliferation. The monocytic hyperplasia is encroaching upon the liver cells which show large cytoplasmic vacuoles and evidence of nuclear degeneration. Oil immersion $\times 960$.

PLATE I

anthracotic but not enlarged. The mediastinal nodes were not remarkable. The heart weighed 500 grams, there was a moderate increase of pericardial fluid, no adhesions, the valves were intact. Bone marrow, secured from ribs, sternum, vertebra and femur, was everywhere abundant, dark red in color, and apparently hyperplastic. The scalp, calvarium and dura mater presented no noteworthy changes. Upon examining the hemispheres, however, the left frontal lobe was seen to be definitely enlarged, extending beyond the midline, compressing the inner surface of the right hemisphere, the convolutions being flattened and the sulci greatly narrowed over the surface. There was a congestion of the capillaries of the pia, the vessels at the base and the basilar and internal carotid arteries showed moderate sclerotic changes. Upon section after fixation a large blood clot filling the entire anterior horn of the left lateral ventricle and involving all of the adjacent tissue was found, being limited by a very thin margin of brain substance.

Microscopic Examination. *Supravital preparations* of the fresh tissues as well as fixed sections were studied. *Brain.* The vessels of the cerebellum and medulla were thickened and their lumen filled with masses of mononuclear cells. In the margin of the clot were to be found many monocytes singly and in large clumps. At some distance from the main hemorrhage there were areas of monocytic cells in the brain substance, many of which were surrounded by definite small hemorrhages. *Liver.* Sections showed an early cirrhosis, venous congestion and small accumulations of monocytes. *Spleen.* The Malpighian bodies were practically obliterated by the hyperplasia of large clear mononuclear cells with vesicular nuclei of varying size and contour and number, and by hemorrhage. There were many eosinophiles and some increase in fibrous tissue. The histo-pathologic picture was not unlike that seen in Hodgkin's disease. *Lymph Nodes.* As many lymph nodes as could be found, including axillary, mesenteric, retroperitoneal, mediastinal and peri-bronchial, were studied, all showing approximately the same pathologic changes: decrease or absence of normal lymph follicles, hyperplasia of large mononuclear cells with bizarre shaped vesicular nuclei, some increase of reticular and fibrous tissue and very many eosinophiles, with an occasional tissue basophile and plasma cell. (See figures 7 and 8, plate 2.) As in the case of the spleen the resemblance to Hodgkin's pathology was striking. *Bone Marrow.* All marrows showed a non-erythropoietic hyperplasia with a diminution in the usual fat content. Intimately intermingled with the myelocytic elements were small groups of monocytes, not present under normal conditions, with the characteristic nuclear abnormalities which suggest a disordered division mechanism. (See figure 2, plate 1.) Erythropoiesis and myelopoiesis were apparently progressing in an orderly sequence except that the myeloid cells showed a greater shift to the left with more of the early myelocytes and myeloblasts present than occur under strictly physiologic conditions. *Kidneys.* Sections showed advanced arteriosclerotic changes, but no monocytic foci.

PLATE II

FIG 5 Case VI. Acute monoblastic leukemia. Photomicrograph of femur bone marrow showing three mitotic figures and the monocytic replacement of myeloid and erythropoietic tissue. Note absence of usual fat cells. Oil immersion, $\times 960$.

FIG 8 Case I. Higher power of the lymph node of figure 7, showing the character of the cells which have displaced the lymphatic elements. Oil immersion $\times 960$.

FIG 9 Case VI. Acute monoblastic leukemia. Bone marrow from the tibia to contrast the monoblastic cells with a megakaryocyte. Oil immersion, $\times 960$.

PLATE II

other than the intravascular accumulations of cells. *Adrenals* An adenoma of the adrenals was revealed on microscopic examination. *Lungs* The alveoli in certain areas were filled with a serous exudate with some neutrophilic leukocytes and fibrin. Other tissues were not remarkable from the standpoint of the monocytic dyscrasia.

In summary, we have a case in which all of the essential criteria for a chronic monocytic leukemia were met. The patient was followed through a 12 months' period without leukemic exacerbation and postmortem confirmation was obtained of death from cerebral hemorrhage upon a hypertensive arteriosclerotic basis. No active tuberculous focus was found. The tissue evidence, particularly in the bone marrow, spleen and lymph nodes, substantiated the existence of a relatively benign leukemic process primarily involving the monocytic strain of cells.

A very similar case has been studied by Dr Hildegard Henderson, formerly associated with us in this laboratory, now of San Francisco, California. The patient a white female aged 53 years, was first seen in July 1930 with complaints of sharp pain on the right side radiating to the back, night sweats, and easy fatigability. The menopause had occurred five years previously. Two months before admission there had been profuse vaginal bleeding which persisted for two weeks and was followed by tarry stools for two weeks. A peri-nephritic abscess, yielding *B. coli*

PLATE III

Maturation of the monocyte as illustrated from selected cases of monocytic leukemia. The maturation of the monocyte and its life cycle have been followed under normal conditions and in experimental tuberculosis, and the evidence now accumulated in the study of monocytic leukemia is supplementary to and in complete conformity with that already adduced. All cells are drawn from Wright's-Giemsa stained blood films.

FIG 1 Case I. Monoblast representative of the type of cell which appeared in increased numbers in the peripheral blood following cerebral hemorrhage in a case of chronic monocytic leukemia otherwise showing no exacerbation during a year's observation. Dense blue cytoplasm, purple mottled nuclear chromatin, fairly large spherical nucleoli. Size 14.5 microns.

FIG 2 Case II. Monoblast of slightly later stage than figure 1 with the dense basophilia partly lost. No azurophilic granules are to be seen but the nucleus is typical. This cell and that of figure 3 were characteristic of the terminal stage in a case which 5 months previously had shown an aleukemic phase. Size 15.2 microns.

FIG 3 Case II. Monoblast with large single nucleolus, but a cytoplasm less densely basophilic than in the two preceding cells. Some mottling of the cytoplasm and a suggestion of beginning vacuolation may be seen, but still no azurophilic granulations. This cell is typical of the majority of monoblastic cells seen in the peripheral blood in the acute stages of the disease. Size 17.5 microns.

FIG 4 Case VI. Young monocyte with two nuclei in an acute case. A few, fine azurophilic granules may be seen in the cytoplasm. Multinucleated monocytes are encountered frequently both in the blood and in the tissues in monocytic leukemia. Size 16.1 microns.

FIG 5 Case V. Vacuolated monocyte, a constant finding throughout the five months' duration of the disease in this case, both in the earlier aleukemic phase and in the terminal acute leukemic exacerbation. Vacuolation occurs much more frequently in the monocyte and in the leukemic monocyte than in the other types of white blood cells. Size 16.8 microns.

FIG 6 Case I. Normal adult monocyte with characteristic indented nucleus and fine azurophilic granulations, this was the predominating type of cell present throughout the period of observation of a year in this patient during all of which time there was a definite elevation of the total leukocyte count with idiopathic monocytosis. Size 16.8 microns.

was found and surgically treated without sequelae or complications. The blood studies at this time showed a total white count ranging from 6,000 to 13,000 with neutrophilic leukocytes 24-43 per cent, lymphocytes 20-40 per cent, monocytes 25-28 per cent, red blood cells 3,470,000, hemoglobin 72 per cent. Since that time the monocytes have gradually increased. In March of this year, the total count was 11,350 and the hemoglobin 85 per cent, our differential from the blood films furnished by Dr. Henderson showed neutrophilic leukocytes 5 per cent, basophiles 1 per cent, faintly basophilic lymphocytes (O) 4 per cent, moderately basophilic lymphocytes (M) 10 per cent, deeply basophilic lymphocytes (Y) 19 per cent, mature monocytes (some vacuolated and some with two nuclei) 57 per cent, young monocytes 2 per cent, non-phagocytic clasmotocytes 1 per cent. No adenopathy and no splenomegaly have been observed at any time. No tuberculous activity can be demonstrated. Aside from an increasing ease of fatigability and "nervousness" there are no complaints. The profound neutropenia is significant as is the "shift to the left" in the lymphocyte formula. A chronicity of the process continues, whatever may be the underlying pathology, and whether the gradually increasing monocytosis without a definitely elevated total count is reflecting a leukemic proliferation of these elements in the bone marrow must await perhaps further studies. No other diagnostic entity can explain the picture at the present time.

MONOCYTIC LEUKEMIA WITH ALEUKEMIC PHASE, LEUKEMIA CUTIS

Case 2 Through the courtesy of Dr. Louis I. Mitchell, of Newark, Ohio, we have been permitted to follow the course of events in a man, W. W. P., aged 63 years, a railroad engineer, whose final illness began with skin manifestations and a leukopenia and terminated some five months later in a typical leukemic exacerbation of monocytic character. Dr. Mitchell is reporting this case in detail elsewhere, so that only a brief resume will be presented here. In December 1931 the patient became conscious of a definitely increasing weakness and anemia. The following April he first noted the appearance of subcutaneous hemorrhagic areas on the inner aspect of each thigh, and at about the same time multiple small firm subcutaneous nodules developed over the lower abdomen, subsequently appearing over the body generally, including the scalp. The testes became enlarged and painful. When first seen by Dr. Mitchell early in April some 200 firm, discrete, movable, subcutaneous nodules were counted. There was no general adenopathy and the liver and spleen were not palpable. Temperature 98° F., pulse 80, respirations 20, blood pressure 120 systolic and 70 diastolic. All search for focal infection resulted in negative findings except for one molar tooth which was immediately extracted without untoward sequelae. Renal function was normal, urine was negative. The total white count was within the limits of normal, 5,000, the differential count revealed 30 per cent qualitatively normal monocytes, 28 per cent lymphocytes, 37 per cent neutrophils, 2 per cent basophiles and 3 per cent eosinophiles. While myelocytes were not observed on this first count every subsequent differential showed from 2-9 per cent myelocytes. There were 3,000,000 red blood cells and 76 gm. hemoglobin per 100 c.c. blood, the erythrocyte fragility was normal, 0.396-0.300, the sedimentation velocity 20 mm. in one hour.

Under arsenic therapy in the form of sodium cacodylate, $\frac{3}{4}$ gr. subcutaneously every 48 hours, a definite reduction in the number and size of the nodules was noted with subjective clinical improvement in the patient, although a more profound leukopenia developed with both neutrophils and monocytes obliterated from the picture for a time (chart 2). Shortly, however, more nodules began to appear even while the earlier ones were fading, and roentgen-ray and radium therapy were instituted on May 10, eleven treatments in all being given during the succeeding

three weeks. Again initial but only temporary success in reducing what a biopsy had shown to be aggregations of mononuclear cells in the deeper layers of the skin attended this therapy. By July the nodules were found to have become resistant to the measures instituted and during the latter part of this month a marked exacerbation of clinical symptoms occurred accompanied by evidences of a rapid increase in the size of liver and spleen. We were again permitted by Dr. Mitchell to study this patient in the terminal stage of his disease, in which the profound anemia and thrombopenia with hemorrhagic diathesis, and definite leukemic blood

CHART 2 The aleukemic phase with marked skin involvement but minimal constitutional symptoms extended over a known period of five months in this case and probably for some four to six months prior to diagnosis. The terminal clinical and laboratory picture of acute monoblastic leukemia showed the total white count of 130,000 to be comprised almost exclusively of monoblastic elements. (See plate 3, figures 2 and 3)

left no doubt as to the diagnosis of the original clinical manifestations. A predominance of very immature mononuclear cells, monoblasts and young monocytes, marked the white cell differential in this case (Plate 1, figure 1, plate 3, figures 2 and 3). On the day prior to death serial counts taken at 15 minute intervals for two hours revealed the erratic maturation and delivery of monocytes in an absolutely disordered mechanism of cellular proliferation which characterizes the leukemic state.⁴⁴ The erythrocyte fragility had changed from the normal of five months before to the leukemic range, 0.471-0.341, the icterus index was 9, the erythrocyte hematocrit was 27, the leukocyte packed cell volume 6.

The tissues secured at a partial postmortem by Dr Mitchell and forwarded to this laboratory for section and study confirmed the clinical and laboratory diagnosis of monocytic leukemia. Liver, spleen, bone marrow and lymph nodes have proved in all cases thus far studied in this series to be of greatest significance from a pathologic standpoint. The liver and spleen in this patient were markedly enlarged. The liver revealed on microscopic examination marked hyperplasia of typical large mononuclear cells with vesicular nuclei of bizarre shape and number with usually one, never more than two, nucleoli. The normal architecture of the spleen was completely destroyed by the overgrowth of monocytic cells, comparable in all respects to the cells found in the circulating blood, in the skin nodules at biopsy and in the other organs mentioned at autopsy. The bone marrow everywhere was hyperplastic with non-hemoglobin bearing elements, the leukemic cells being quite distinct morphologically from the myelocytic cells among which they were scattered and upon which their rapidly proliferating mass was obviously encroaching.

This case exemplified three interesting manifestations of monocytic leukemia: (1) initial chronicity, (2) an initial leukopenic or aleukemic phase, (3) spontaneous, specific, widespread proliferation in the general connective tissues of an indigenous connective tissue element, the monocyte, at a time when the absence of any excess of these cells in the peripheral blood eliminated the possibility of an infiltrative mechanism to explain the formation of the subcutaneous nodules. This last evidence is akin to that obtained in the experimental studies of tuberculosis, in which tissue and organ proliferation of monoblasts, monocytes and epithelioid cells definitely precedes the appearance of increased numbers of monocytes in the peripheral circulation. This sequence of events holds both for the disease itself,¹² and for the reactions following the exhibition of tuberculo-phosphatid into the body.²

Cases 3 and 4 have been studied through the courtesy of Dr S T Mercer, of the Vanderbilt Clinic, the Medical Center, New York City, who recognized and diagnosed the blood dyscrasia and its type in these two patients from the clinical history and character of the skin lesions, the latter having presented as one of the chief complaints in the syndrome. Both were acute cases of rather short duration, with no preceding illness, and with definite leukemic blood pictures of typical, characteristic monocytic dominance. One of these patients we saw in person, and had the opportunity of studying the supravital characteristics of the cells of the blood, as well as those presented in the fixed films. The other was studied only through the fixed blood films and the sectioned material secured at biopsy when representative skin nodules were obtained. The findings already listed as cytologically significant in monocytic leukemia were all present in these cases and the detailed data important to the recognition of monocytic leukemia cutis and its differentiation from the skin lesions in leukemic states of other cytologic origin and from non-leukemic dermatoses, are being presented by Dr Mercer elsewhere.

Case 5 is again a case referred to us for an opinion as to the differential diagnosis by Dr E W Mitchell of Cincinnati, Ohio. Dr Mitchell kindly furnished us with a series of blood films covering the period of observation from June 15, to December 15, 1933, showing the gradual transition from an initial aleukemic state into the terminal leukemic syndrome of typical monocytic predominance (Chart 3). The history and clinical course are quite similar to those of Case 2, except for the absence of skin manifestations, the duration of the disease in each instance

was between five and six months. From the very beginning in this case, a careful survey of the cells in the peripheral blood revealed not only a relative increase in the number of monocytic cells but also qualitative changes which could not be mistaken. As is so much more frequently found with monocytes than with the other white blood cells, very many of these specific elements showed large, clear, vacuolar

CHART 3 During the aleukemic as well as in the leukemic phase of this case the qualitatively changed and characteristic monocytes (see plate 3, figure 5) dominated the differential count. Myelocytes were present in the earlier months but disappeared as did most of the non-monocytic elements in the terminal stages of the disease, indicating extensive bone marrow invasion and replacement. The lymphocytes remained present longer and in more nearly normal total numbers than did the granulocytes.

degenerations (Plate 3, figure 5). Characteristic nuclear chromatin and cytoplasmic turbidity with azurophilic dust completed the identification. In the beginning myelocytes were present but as the peripheral count rose both mature neutrophils and myelocytes steadily decreased in relative and absolute numbers, the lymphocytes not so markedly.

It is important both from the standpoint of prognosis and of treatment to separate such cases as this one from the Schultz syndrome of agranulocytosis and from other leukopenic states,⁷⁰ and this may best be accomplished by an adequate qualitative study of the white cells

ACUTE MONOCYTIC LEUKEMIA

Our cases of fulminant monocytic leukemia have presented the typical acute manifestations with which the physician is beginning to be familiar, since the great majority of case reports now appearing in the medical literature deal with this striking symptomatic syndrome, which calls for immediate hospitalization and emergency measures

Case 6 G S, white female, aged 34 years, was first admitted to University Hospital, June 27, 1931 complaining of drowsiness, headache, fever (104° F) and photophobia, of one week's duration with a loss of eight pounds in weight during this period. Past history was entirely negative. Family history has no bearing upon this or the subsequent illness. Physical examination: temperature 99° F, pulse 88, respirations 20, blood pressure 118 systolic and 70 diastolic. The mouth showed considerable dental work but teeth and gums were in good condition. There was no lymphadenopathy. The thyroid gland was enlarged and nodular, especially on the right side. The chest, abdomen, and extremities were negative. The urine examination was negative, the Wassermann and Kahn tests negative, the basal metabolic rate minus seven. Total white cells, 11,250, differential-neutrophilic leukocytes 70 per cent, lymphocytes 29 per cent, monocytes 1 per cent, total red cells 4,520,000, hemoglobin 75 per cent (Dare). On discharge July 1, 1931 the diagnosis was acute upper respiratory infection, adenoma of thyroid, non-toxic.

On December 12, 1932, 17 months later, the patient again sought admission to the University Hospital with the complaint of severe oral infection. Early in November the patient had suffered from tonsillitis followed by an otitis media which had ruptured spontaneously and drained. In the middle of November gingival abscesses about the first and third upper molars were surgically drained. Before the end of the month she had had seven abscesses incised by her dentist. The oral involvement grew steadily worse until finally a medical consultation was advised.

The patient when admitted December 12 was obviously acutely ill. An extensive necrotizing process had invaded the left maxilla, practically all teeth both above and below appeared to be involved with a purulent gingivitis, and the breath was markedly offensive. The jaws could only be opened a fraction of an inch. The cervical nodes were greatly enlarged, painful and tender. At the time of admission she had been menstruating profusely for eight days and gave a history of 10 days of profuse hemorrhage following the onset of the previous menses (November 3). Frequent chills and fever had been experienced since the onset of the present illness with persistent nausea and on two occasions vomiting. The temperature on admission was 102.4° F. The following day the temperature reached 104° F, and for the most part this elevation (104° to 105°) was maintained throughout the course of the disease. The pulse ranged from 120 to 150, the respirations from 30 to 50. The blood pressure was 110 systolic and 58 diastolic. Moderate enlargement of the lymph nodes in all parts of the body was noted. The nodular cystic thyroid found on a previous admission was confirmed. The chest was essentially negative. The spleen was palpable and tender 6 cm below the left costal border, the liver was not palpable. There were no other palpable masses and no areas of tenderness. Reflexes and extremities were negative. The white count on admission was 99,000.

with 68 per cent young monocytes (plate 3, figure 4), 2 per cent monoblasts, 5 per cent mature active polymorphonuclears, 16 per cent myelocytes with none younger than the myelocyte "B" stage, 8 per cent small and 1 per cent intermediate sized

CHART 4 This graph depicts the blood findings in a patient with in acute, rapidly fatal, fulminant type of the disease, of six weeks' duration only, with monoblasts dominating the peripheral blood picture, 90,000 per cu mm, but with severe anemia and myeloblasts and myelocytes present to the extent of from 10,000 to 20,000 per cu mm, indicating progressive bone marrow invasion without complete replacement

lymphocytes See chart 4 for a summary of the blood findings in this case during the period of hospitalization. The total red cells were 1,310,000, hemoglobin 7.4 gm per 100 cc blood, erythrocyte hematocrit 13, leukocyte packed cell volume 9,

erythrocyte sedimentation 75 mm in 1 hour, fragility 0.471 to 0.300, icterus index 10, Wassermann negative, blood group, type IV Blood sugar 38 mg per 100 cc blood, NPN 40 mg, uric acid 11.1 mg Blood iodine 90 gammas % (normal 12)

Treatment consisted of two blood transfusions on December 15 and December 23 respectively, of two deep roentgen-ray exposures over the splenic area on December 17 and December 21, and of repeated large quantities of glucose-Ringer's solution intravenously Death occurred on December 27, approximately six weeks from the first onset of symptoms referable to the leukemia

Autopsy was performed December 28 by Dr Harry Rinehart, Pathologist to the University Hospital The anatomical diagnosis included acute, diffuse, necrotizing, semi-membranous gingivitis, pharyngitis, tonsillitis, hemorrhagic cellulitis of the left cheek, bilateral diffuse, nodular thyroid with cystic degeneration and hemorrhage, acute suppurative cervical adenitis, generalized adenopathy of moderate degree, bilateral bronchopneumonia, parenchymatous degeneration of the heart, enlargement of the liver, splenomegaly, acute ulcerative colitis, pigmented areas of old hemorrhage in mucous membrane of ileum and cecum, recent hemorrhage in urinary bladder, chronic adhesive perimetritis lacerations of the cervix, bilateral acute parenchymatous nephritis, bone marrow from humerus, femur, tibia, sternum, ribs, vertebra had the "gross appearance of that found in myelogenous leukemia", edema of the meninges of the brain

Microscopic examination revealed *Bone Marrow* The marrow everywhere was cellular, of a mottled gray color with very few normal appearing red areas Supravital studies revealed practically complete absence of fat and of erythropoietic foci, and but one or two granular cells were found in each oil immersion field A very rare megakaryocyte was seen The hyperplasia was found to comprise chiefly medium sized mononuclear cells with large vesicular nuclei and a finely mottled cytoplasm, many mitotic figures reflecting the rapidity of the growth Multinucleated cells were frequently encountered containing from two to five nuclei, not unlike the Dorothy Reed-Sternberg cells of Hodgkin's disease The multinucleated cells were of the same type as the predominating mononuclear cells and the entire group were distinctly foreign to the normal cytology of bone marrow Cover slip preparations of emulsions of marrow from humerus and tibia in autogenous blood plasma, stained with Wright's-Giemsa, confirmed the monocytic character of these cells Fixed sections further established the identity of the cellular response in the marrow with that of the circulating monocytic cells of the blood (Plate 2, figures 5 and 9)

Lymph Nodes Fixed sections from the inguinal, iliac, lumbar, retroperitoneal, mesenteric, mediastinal, axillary and cervical nodes were studied An atrophic thymus did not partake of the monocytic hyperplasia found elsewhere in lymphatic tissue Hemorrhage was commonly encountered The follicles were markedly atrophic with germinal centers either entirely absent or infiltrated with the large mononuclear elements, which also filled the sinuses Monocytic mitoses and eosinophilic granulocytes were prominent *Spleen* Weight 650 grams red, soft, smooth capsule, on cut section uniform reddish brown color with decided increase in pulp substance and an absence of visible Malpighian bodies The architecture was markedly altered by the overgrowth of monocytic cells, which had invaded the lymph follicles and which filled the dilated sinuses, occasional myelocytes and clasmotocytes, many mitotic figures were found in the monocytic cells *Liver* Weight 2350 grams, extended 5 cm below the costal border, showed parenchymatous degeneration, some focal mononuclear aggregations, and sinuses filled with monocytes *Lungs* Bronchopneumonia, edema with increased monocytes in alveolar septa and vessels, no evidence of tuberculosis *Heart* Weight 325 grams No monocytic accumulations in tissue other than those within vessels Moderate parenchymatous degeneration *Pancreas* and *adrenal* normal *Kidneys* Monocytic infiltrations with

definite scarring and tubular degenerations, glomerular tufts and capillaries showed abundant monocytic cells. *Stomach, duodenum, jejunum and ileum* showed evidence of old and recent punctate hemorrhages, the colon was the seat of definite ulcerative necrotic lesions with polynuclear and monocytic infiltrations. The *brain* showed only an intravascular increase of monocytes without tissue increase.

In brief, as was to be expected, all organs and tissues showed the intravascular increase of monocytic cells, and in addition, in those places where connective tissue reticular "mesenchymal rests" exist normally, loosely organized foci of characteristically disoriented monocytic elements were found, proliferating wildly as judged from the numerous mitotic figures, and more or less completely displacing normal structures. Bone marrow, lymph nodes and spleen, the principal sites for blood cell generation, present the most marked pathologic changes in monocytic leukemia, thus serving to demonstrate still further the close relationship which exists between the three types of white blood cells and the possibility of a common ancestry.

Case 7 D M, a white boy, aged five years, referred by Dr A G Helmick, was admitted to the Research Service of the University Hospital November 2, 1933, complaining of increasing weakness, pallor and swollen glands. On September 5, 1933 the patient complained of sore throat and suffered a gastric upset. One week later definite cervical adenopathy was observed. During the following month the cervical nodes fluctuated from time to time in size. About the end of September the patient developed a severe upper respiratory infection with secondary sinus involvement. An increasing disinclination to normal activity, increasing pallor, persistent adenopathy and the development of mouth breathing led to the diagnosis of tonsils and adenoids. Fortunately, prior to operative interference a routine blood study was requested and the following report returned: PMN 3 per cent, lymphocytes 97 per cent, hemoglobin 30 per cent. It was at this point that we first saw the patient. Bleeding from the nose difficult to control had occurred on two occasions and oozing from the gums was becoming increasingly troublesome. Spontaneous subcutaneous hemorrhages had appeared in addition to a recently noted increased susceptibility to bruises.

The past and family histories were unessential.

On physical examination the patient revealed temperature 100° F, pulse 128, respirations 28, blood pressure 104 systolic and 50 diastolic. The outstanding points were pallor, marked cervical adenopathy and a noisy type of mouth breathing. He was restless, active, but tired easily. Discolored areas were noted scattered over the entire body, the nail beds showed some cyanosis and the lips were dry and encrusted with dried blood. The conjunctivae were pale, but the eyes and eye grounds showed no hemorrhages. The nasal passages were occluded by excessive pharyngeal lymphoid hyperplasia, there was a posterior nasopharyngeal drip producing a gurgling type of mouth breathing, and necessitating frequent coughing, the tonsils were greatly hypertrophied with reddened pillars and small faucial isthmus. The gums were edematous, bleeding easily, and several small blood clots were seen about the teeth. A very fetid and offensive breath was apparent. On the dorsum of the posterior third of the tongue were two small hemorrhagic ulcers. The cervical nodes were prominent, firm, discrete, freely movable, not adherent to the skin, of variable size and slightly tender, the nodes at the angle of the mandible were largest, the submaxillary slightly smaller, those in the anterior triangle smaller than those in the posterior. The axillary nodes were about 2 cm in diameter, the epitrochlears and inguinals were also readily palpable. The chest was negative. The spleen

was enlarged, firm, extending 4 cm below the costal margin in the nipple line, but the liver margin was not definitely palpated. Genitalia, extremities and reflexes were normal.

Laboratory findings Total white count 20,600, supravital differential PMN 5 per cent, PMB 7 per cent, PME 5 per cent, myelocytes 10 per cent, small lymphocytes, 19 per cent, monocytes 49 per cent, monoblasts, 5 per cent. Blood platelets 6000 per cu mm. Total red cells 760,000 hemoglobin 34 gm per 100 c.c. blood, reticulocytes 32 per cent, hematocrit 9 erythrocyte fragility 0.412 to 0.300. The basal metabolic rate was plus 13. The sequence of events as reflected in the blood studies and the therapeutic measures employed may be followed from chart 5. Blood transfusion was performed as an emergency measure on admission and was repeated as often as was necessary during the succeeding weeks to control the hemorrhagic tendencies and provide a maintenance supply of red cells while attempts were being made to reduce the condition to a more chronic stage. Following the ineffectiveness of arsenic medication, roentgen-ray treatments were instituted and either a spontaneous exacerbation of the disease occurred or the irradiation actually accentuated the process. The total white count increased, the spleen and lymph nodes continued to enlarge, subcutaneous skin nodules appeared, and within one month death occurred. A postmortem examination was refused.

Myelocytes of the A, B, and C type were present at all times and an occasional myeloblast was encountered, but no irregularity in the division figures or in the symmetry of the nuclei and nucleoli characteristic of leukemic states was found. The lymphocytes were entirely within the qualitative range of normal at all times also, and the final exacerbation was reflected almost entirely in an increase in the monocytic elements.

THE PROBLEM OF MIXED LEUKEMIA

It will have been noted that in each of the cases cited in this series there have been recorded "shifts to the left" in both lymphoid and myeloid series. Nevertheless qualitative as well as quantitative data have been presented which suggest, and in four of the cases postmortem studies have confirmed, the primary incrimination of the monocyte rather than the other cell strains. Our remaining cases of monocytic leukosis have presented an even more striking mixture of cell types in the peripheral circulation, and undoubtedly represent the type of case which has been discussed in the literature as mixed leukemia. Certain pertinent data have been accumulated, however, which lead us to question a sound underlying pathologic basis for this clinical diagnosis. A mixed leukemia in which all three strains of white cells are equally involved is, of course, theoretically possible though unlikely, if our present concepts of their common stem cell origin are correct (diagram 1). It is only in so-called monocytic leukemia that we have encountered this liberal sprinkling of myelocytes and young lymphocytes, together with a monocytosis. In the classic myeloid or lymphoid syndrome the monocyte is never present in increased numbers, nor does it show peculiar qualitative changes, and usually the cell strain principally involved represents 95 to 99 per cent of all cells found in the blood. In the cases in which an equal quantitative distribution of the three strains of white cells has occurred in the blood with immature elements present from

each, it has been possible, nevertheless, by applying the criteria now available for the appraisal of normal cellular development, as contrasted with abnormal and disordered maturation, to distinguish the primary from the secondary involvement

We have illustrated elsewhere¹⁴ the amitotic nuclear division occurring in the myeloid elements in subacute myeloblastic leukemia. In this series the same asymmetry and atypical cellular division were noted in the monocytes. All of the cellular elements in the circulation showed some mitotic activity in the cases of monocytic leukemia. It was only among the monocytes, however, that we noted unequal division of nucleoli and asymmetrical distribution of nuclear chromatin, incomplete mitotic spindles with resulting nuclei of unequal size. Both myelocytes and young lymphocytes divided normally and the resulting multinucleated cells contained symmetrical and equally divided nucleoli. At postmortem the wide dissemination of monocytic hyperplasia, particularly at the sites and at the expense of myeloid and lymphoid generation, further confirmed the interpretation of primary monocyte pathology implied from the studies of the peripheral blood. These points will be presented in detail elsewhere and represent a distinct contribution which we believe the study of monocytic leukemia can make to a better understanding of the fundamental metabolic or environmentally conditioned constitutional disturbances upon which the leukemic states are engrafted.

ETIOLOGIC CONSIDERATIONS

Although the nature of the disorder, which permits or causes leukemic hyperplasia of monocytes, is not known, the mechanism of monocytosis in other pathologic states is more apparent. In general, the existence of either or both of two circumstances has resulted in a stimulation to monocytic proliferation: (1) the opportunity or need for phagocytosis of non-pyogenic bacteria or of other particulate matter, (2) the presence of an excess of lipoidal substances, occasioned either by certain disorders in the normal metabolism of fats, or by the liberation *in vivo*, or the parenteral introduction, of foreign monocytogenic lipoids.

We have already cited instances in which the phagocytic function of this cell strain has formed the basis for increased activity, and the clear cut results obtained in the studies with tuberculo-phosphatid immediately suggest the monocytogenic potentialities of other lipoids. Conversely, the cellular reactions in certain diseases known to involve disturbances in lipid metabolism appear to be largely of monocytic origin, though the evidence for strict cytologic identity is as yet inconclusive in some.

In certain cases of diabetic coma with lipemia, large foam cells not unlike hypertrophied monocytes may be found in the spleen and to a lesser extent in the lymph nodes, tissues normally the site of origin for monocytes. Of particular interest and probably of importance in considering this aspect of the problem is the apparent relationship of faulty lipid metabolism to

monocytic proliferation as observed in the so-called xanthomatoses. In Niemann-Pick's disease large phagocytic cells storing lecithin and phosphatid and arising from the reticulum cells⁷¹ are not only disseminated widely throughout the body in enormous numbers but may be found invading the blood stream. Whether this phenomenon is the result of a need for increased phagocytic function as suggested by Bloom⁷² or represents a specific stimulus from the blood lipid as suggested by the work on tuberculo-phosphatid and lecithin² is uncertain. A similar origin for the increased numbers of phagocytic cells noted in Hand-Schuller-Christian's disease is probable, the lipid deposition and lipemia consisting chiefly of cholesterol-fatty esters⁷³. The accumulation of fat-laden phagocytes in this disease forms a very characteristic granulation tissue which is readily converted into fibrous tissue, often causing severe anemia when it occurs in the bone marrow. The mechanism is not unlike that observed in Hodgkin's disease. In Gaucher's disease a lipemia consisting of the cerebroside, kersin⁷⁴ results in the formation of lipid storage cells in the tissues which are often multinucleated in type and suggest morphologically the giant cells of tuberculosis and Hodgkin's disease. In the monocytes of monocytic leukemia itself we have noted, as have others, the frequency with which vacuolar, fatty (?) degeneration is seen (plate 3, figure 5) in marked contradistinction to its occurrence in the cells in other types of leukemia.

Thus, tuberculosis, Niemann-Pick's disease, the Schuller-Christian syndrome, Gaucher's, and Hodgkin's disease, while differing clinically and pathologically, nevertheless have certain features in common. A generalized adenopathy with splenomegaly characterize the last four and may be present in tuberculosis. The development of granulomatous tissue with scar formation has been a common finding, more particularly in tuberculosis, Christian's disease and Hodgkin's disease. Large mononuclear, and multinucleated giant cells occur, being especially prominent in tuberculosis, Hodgkin's disease and Gaucher's disease. Some form of lipid disturbance has been shown to be present in each of these conditions except Hodgkin's disease, and in each, phagocytic cells probably of the monocytic strain, have reflected the major cellular response.

In typical Hodgkin's disease the characteristic blood picture includes an absolute, as well as a relative, monocytosis, together with a leukopenia, lymphopenia, eosinophilia, and anemia, the reversed monocyte-lymphocyte ratio reflecting the hyperplasia of monocytes and fibroblasts in lymph nodes and frequently in bone marrow. The etiology is as yet unproved, but if the avian tubercle bacillus or other acid fast organism is involved, as has been suggested,⁷⁵⁻⁷⁶ the lipid basis for the cellular pathology would be clear here also. Hodgkin's disease provides an interesting transition between the group of diseases showing monocytosis and the group of pathologic states which may be said to be leukemic in nature. The histopathology of lymph nodes and spleen from our cases diagnosed as monocytic leukemia (especially Case 1) was indistinguishable from that of typical Hodgkin's

disease. Subsequently we have found an instance in the literature⁵² of Hodgkin's disease reported as terminating in monocytic leukemia. Dame-shak⁷⁷ has noted the similarity between, and possible common etiology of so-called aleukemic reticulosis and Hodgkin's disease. It would seem that any approach to an understanding of the cellular reaction in Hodgkin's disease, the xanthomatoses and monocytic leukemia should be made with a full recognition of the basic studies on the mechanism of monocytosis in other diseases, more particularly those in tuberculosis with tuberculo-lipoids. This, of course, does not deny the possible neoplastic nature of some members of this group, but it does suggest an explanation of some of the features found in these diseases difficult to reconcile with the theory of malignancy.

DISCUSSION

In any study involving the cells of the blood and the organs and tissues from which they arise, the principal difficulty commonly encountered at the present time is the adequate differentiation of the mononuclear elements. Under pathologic conditions a "shift to the left" in any or all of the cell strains complicates the picture still further, with monoblast, myeloblast and lymphoblast presenting a minimum of criteria for differential identification. In plate 3 may be seen the transitional stages in the maturation from monoblast to mature monocyte as observed with the Wright's-Giemsa staining technic in the blood of patients with monocytic leukemia. The monoblast embodies characteristics which after careful study by comparison and contrast with myeloblast and lymphoblast usually make for its definite recognition. The density of the basophilia of the cytoplasm (plate 3, figures 1, 2, 3) is midway between that encountered in the lymphoblast and the lighter blue of the myeloblast. Usually one nucleolus, never more than two spherical nucleoli, are found in the characteristic, purple staining, splotchy chromatin of the monocyte nucleus. Figure 2 is typically representative of the gradual reduction in basophilia of the cytoplasm, which occurs during the early stages of maturation, to a maintained, opaque, mottled, cytoplasmic background within which appear many fine, scattered azurophilic granules in the mature state. Multiple nuclei (figure 4) are frequently encountered and in most of the leukemic cases there are from few to many highly vacuolated cells among the monocytes (figure 5). In the more chronic states many of the monocytes are qualitatively entirely normal (figure 6). The monocytes in the peroxidase stain react positively but usually may be distinguished from the granulocytes in the amount and distribution of oxidase granules. In the supravital studies with neutral red and Janus green, which always should accompany and supplement the fixed film surveys, the characteristic surface film motility, scattered fine blue-green mitochondria and a rosette of neutral red vacuoles identify the monocyte. These finer cytological differentiations are not apparent upon superficial casual examination, but with experience become increasingly de-

pendable. The experimental studies in tuberculosis formed the basis for the first careful analysis of the life cycle of the monocyte, revealing the epithelioid "shift to the right" in that disease. The study of monocytic leukemia provides the material for a similar appraisal of the maturation phases in this strain of cells with variable degrees of "shift to the left" toward the monoblastic level revealed.

In those cases which have come to autopsy in our series we have studied the various tissues carefully in an attempt to ascertain the origin and nature of the new growth of cells responsible for the abnormal blood picture. Always the principal sites of cellular hyperplasia have been in lymphoid tissue, spleen, liver and bone marrow. Arising diffusely in intervascular areas the characteristic large mononuclear monocytes have been found scattered loosely between and more or less completely displacing the normal cells. Many mitotic figures may be found, and deeply indented vesicular nuclei, frequently multiple and of varying size within the same cell (plates 1 and 2), serve to produce a cytological picture in the tissues altogether different from that seen in either myeloid or lymphatic leukemia. Studies of normal monocytic differentiation in the spleen¹³ and peripheral lymph nodes¹⁴ and of pathologic proliferation in experimental tuberculosis or after the injection of the lipid fractions from tubercle bacilli² have revealed the potentialities of latent connective tissue elements for monocytic differentiation when the proper stimuli are present. Fibrous connective tissue may also increase somewhat at times and the similarity between the pathologic tissue in monocytic leukemia and that found in Hodgkin's disease for example has at times been startling. The study of the five cases of monocytic leukemia coming to autopsy has served to reaffirm the evidence of the mesenchymal connective tissue origin of the monocyte adduced in the long series of studies already referred to in which this cell has been subjected to careful analysis. The fact that the monocytic hyperplasia in the leukemia of that type has occurred predominantly in those locations where the other white cell elements, myelocytes and lymphocytes, normally differentiate, further suggests the close relationship which we believe exists between the three strains of white cells in their earliest beginnings.

We have cited the wide range of clinical manifestations observed in our series of cases of monocytic leukemia, and the marked difference in acuteness and severity of the disease. This is of course, in conformity with the observed facts in the other leukemic states and in disease in general. Either the etiologic factor varies in its severity or in the duration of its effect upon the tissues or, as seems more likely, the constitutional reaction of the individual provides the conditioning factor which determines in the last analysis whether the pathologic trend is to be rapidly progressive or relatively quiescent. Each patient must therefore be studied quite objectively and from other standpoints than the blood picture, before an intelligent prognosis may be given. Just where the dividing line between a so-called benign, idiopathic monocytosis and chronic monocytic leukemia

should be drawn is not always clear, but the benefit of the doubt should be given the patient as long as the diagnosis of leukemia carries with it the implications of a fatal malignancy

SUMMARY

1 Clinical studies are aiding, and in turn are being distinctly furthered by a proper evaluation of the monocyte

2 The monocyte is an independent entity, with life cycle and functions specific to its own peculiar endowments

3 In tuberculosis the monocyte has been shown to reflect, and to be an important part of, the cellular reactions to the acid fast bacilli and more particularly to the lipoids elaborated by this group of organisms. When properly appraised and interpreted in conjunction with the other cellular elements of the blood and in the further light of available clinical and laboratory data, prognosis in this disease and an accurate prompt estimation of the effectiveness of any given therapeutic measure become possible

4 In Hodgkin's disease, syphilis, pneumonia, the xanthomatoses and in other pathologic states the monocyte if properly evaluated may contribute to the diagnosis of the disease and to the management of the patient

5 During the past four years 12 cases of monocytic leukemia have been diagnosed and nine have been carefully studied clinically with five post-mortem surveys

6 The problem of differentiating the leukemias and more particularly the question of mixed leukemia has been discussed and data submitted upon which to base judgment in the critical analysis of the individual patient

We desire to acknowledge the assistance of our several Residents, Drs S T Mercer, Lowell A Erf, and Malcolm M Hargraves, on the Research Service, University Hospital, in the care and study of individual cases in the series here reported

REMARKS ON THE DIAGNOSIS OF CORONARY OCCLUSION *

By LOUIS HAMMAN, M D , F A C P , *Baltimore, Maryland*

ABOUT eight or ten years ago, at a time when I was much interested in the clinical manifestations of coronary occlusion, I was often asked to see patients with symptoms of collapse following a severe attack of pain in the chest and under these circumstances had the satisfaction of pointing out how clearly and simply the diagnosis of coronary occlusion could be made. However, these opportunities have come very, very rarely during the past few years. At the present day the humblest practitioner of medicine and the most recent graduate are so thoroughly familiar with the clinical picture of this tragic event and so acutely alive to its recognition that the opinion of a consultant is seldom needed to suggest the diagnosis. Indeed, the diagnosis is frequently and readily proposed and having passed through the earlier period when it was seldom even thought of, I am now often surprised by being asked to see patients with coronary occlusion who are really suffering from some other disorder. It is astonishing how rapidly information about the condition has spread through the profession and with what eagerness and enthusiasm the knowledge has been applied. Now, when almost every sudden, severe pain in the chest of a person past middle life is at once called coronary occlusion, seems the appropriate time to sound a warning. There are other diseases of the heart, lungs and abdominal organs which may so closely resemble coronary occlusion that they are often distinguishable from it only with great difficulty and sometimes not until autopsy discloses the real state of affairs. It is not my purpose to discuss in detail the differential diagnosis of coronary occlusion. I wish only to dwell upon five conditions which in my experience have occasionally been confused with it. These conditions are upper abdominal disease, pericarditis, pulmonary embolism, rupture of the aorta and interstitial emphysema of the lungs.

I UPPER ABDOMINAL DISEASE

The diagnostic difficulty of distinguishing between coronary occlusion and upper abdominal disease is often very great. In spite of the fact that the similarity between the two conditions is generally well known the difficulty arises again and again. Sometimes the course of events quickly dispels uncertainty but at other times it is almost impossible to make a confident decision. The matter has been so often and so widely discussed that no more is necessary than briefly to mention it. On four occasions the difficulty has greatly puzzled me.

On one, the patient was operated upon for what was thought to be a perforated peptic ulcer. The peritoneal cavity and abdominal organs were

* Read at the Chicago meeting of the American College of Physicians, April 18, 1934

found to be normal. Later a period of auricular fibrillation, the transient appearance of a pericardial friction rub and the occurrence of pulmonary embolism established the correct diagnosis.

On another, gall-stone colic with infection of the bile passages and gall-bladder was accepted as the explanation for pain, fever, leukocytosis and a slightly swollen, tender liver. Only weeks later was the error corrected when the unmistakable signs of beginning myocardial insufficiency appeared.

On still another, a prominent surgeon, called to see a man with intense upper abdominal pain, decided the symptoms were due to coronary occlusion not to gall-stones and asked a physician to take charge of the situation. However, two days later the patient was deeply jaundiced.

On the fourth, surgeons and physicians argued pro and con for two days, when finally the characteristic symptoms of coronary occlusion appeared.

II PERICARDITIS

Pericarditis may come on with sudden severe pain and the pain be quickly followed by the symptoms of myocardial insufficiency. Under these circumstances the severe pain, the pericardial friction, the fever and leukocytosis, the shortness of breath, the cyanosis, the congestive failure may simulate the manifestations of coronary occlusion. Again and again this diagnosis is made when patients with pericarditis are first brought into the hospital. On two occasions I have been consulted by young men under 40 who have told me that a diagnosis of coronary occlusion had been made a year or two before on the evidence of severe pain coming on abruptly and accompanied by a pericardial friction, fever, shortness of breath and certain abnormalities in the electrocardiogram. After recovery from this illness they had remained perfectly well and had had no symptoms whatsoever referable to the circulatory system. The examination at the time of their visit to me failed to disclose the slightest sign of any abnormality about the heart or circulation. I cannot cease wondering if they may have had pericarditis and not coronary occlusion. I add a brief summary of a few illustrative cases.

CASE I

A colored laborer, 29 years of age, entered The Johns Hopkins Hospital on June 15, 1933, complaining of severe pain over the heart. For a number of years he had been very obese, weighing as much as 240 pounds. The gain in weight had come on rather quickly about seven years before. During a year and a half before his admission to the hospital he had been treated in the Orthopedic Clinic for genu valgus and flat feet.

At four o'clock on the afternoon of the day before his admission the patient was awakened from a nap by excruciating pain beneath the upper end of the sternum. He sat upon the edge of the bed gasping for breath and moaning with pain. His misery continued unabated during that night and during the whole of the next day. In the evening he was persuaded to enter the hospital.

Examination Temperature 102° F, pulse 120, respirations 48, blood pressure 112 systolic and 50 diastolic

The patient was an obese young colored man. He lay propped up in bed with a moderate amount of dyspnea, complaining of intense pain over the heart. The least movement greatly increased the pain. Breathing was rapid and shallow. Obviously he was very ill. There was no cyanosis, no cough. The eyes were normally prominent. The pupils were equal and reacted actively. The eye movements were normal. The fundi showed no noteworthy abnormality. The nasal septum was perforated. The teeth were in very poor condition and there was marked pyorrhea. The tonsils were large and small patches of white exudate were seen on the left tonsil. The glands at the angle of the jaw were palpable, otherwise there was no glandular enlargement. The thyroid was normal in size. The trachea was in the midline, there was no tracheal tug. The chest was well formed and symmetrical. Over the bases of both lungs there were dullness, diminution in the intensity of the breath sounds and many moist râles. These signs were more marked on the left side than on the right except that the râles were much more numerous on the right. Over the heart there was a faint rippling pulsation in the fourth and fifth interspaces. The apex beat could not be seen or felt. The area of cardiac dullness was greatly enlarged and had a somewhat globular contour. Dullness extended 5 cm to the right and 12 cm to the left of the midline. The sounds were distant and faint. A soft systolic murmur was heard at the apex. The second pulmonic sound was accentuated. There was gallop rhythm. A loud to-and-fro pericardial friction was heard all over the heart. The pulse was regular, soft, not paradoxical. The peripheral vessels were not thickened. The abdomen was prominent and obese. Examination of the abdomen was difficult with the patient in a sitting position. There was no ascites. The liver seemed to be somewhat enlarged, the edge indefinitely felt 3 cm below the costal margin. There was minimal pitting edema over the shins. The neurological examination was negative.

Course in the Hospital The patient was desperately ill on admission and although from time to time there seemed to be a little improvement in his condition, the course was downhill. He died on the twelfth day after entering the hospital. During this period he always was very drowsy. He complained little but always had pain over the heart which was much increased by breathing and by changing posture. The area of cardiac dullness steadily increased so that at the time of death it was much larger than when he entered the hospital, the area measuring 6 cm to the right and 16 cm to the left of the midline. How much of the dullness was due to enlargement of the heart and how much to pericardial thickening and effusion it was impossible to say. There never was more than the slightest edema. The liver was not greatly enlarged, extending only a little below the costal margin. The lung signs increased in extent. At first there were the signs of fluid in both pleural cavities, later there seemed to be in addition evidence of consolidation particularly in the right lower lobe. Four attempts were made to tap the pericardium from different positions. The attempts made over the heart all failed to yield fluid. Two punctures in the left axillary area yielded a small amount of fluid, on each occasion about 150 cc. However, one could not be certain that this fluid came from the pericardial sac because there was fluid in the left pleural cavity. The fluid from the first successful tap was hemorrhagic, the cell count being red blood corpuscles 300,000, leukocytes 770. The second successful tap gave a turbid, yellow fluid of specific gravity 1.021, containing 10 grams of albumin per liter. The cell count was red blood cells 220,000, leukocytes 3200. A differential count of the leukocytes showed 62 per cent polymorphonuclears, 35 per cent lymphocytes and 3 per cent monocytes. The right pleural cavity was tapped on June 21 and 50 cc of fluid were removed. The patient finally became very weak with extraordinarily rapid, panting breathing and on June 27 he was found dead in

bed On admission the pulse was rapid and regular, later it was rapid and totally irregular, and shortly before death it again became regular

In this patient the sudden severe pain followed at once by the symptoms of myocardial insufficiency aroused the suspicion that he might have coronary occlusion or rupture of the aorta with the formation of a dissecting aneurysm After a few days of observation it was apparent that he had pericarditis On the wards it was thought that he had tuberculous pericarditis, but autopsy demonstrated that it was rheumatic

The anatomical diagnosis reads as follows Rheumatic vegetations on mitral and aortic valves, rheumatic scarring of mitral, aortic and tricuspid valves, scarring of myocardium, cardiac hypertrophy, acute rheumatic pericarditis, bilateral sero-fibrinous pleurisy, pulmonary edema, thrombosis of a branch of the pulmonary artery right upper lobe, slight lobular pneumonia, chronic passive congestion of lungs and liver, acute splenic tumor, diffuse scarring of pancreas and testes, beginning arteriosclerosis, obesity

CASE II

A colored laborer, then 37 years of age, came to the Medical Clinic of the Out-Patient Department of The Johns Hopkins Hospital on December 8, 1926, complaining of a cold which he had had for a week The physical examination on that occasion showed no important abnormality The heart was normal in size, the sounds perfectly clear The impression was expressed that the patient had an acute upper respiratory infection A roentgenogram of the chest showed the lungs to be clear The Wassermann reaction on the blood serum was strongly positive, and the patient was referred to the Syphilis Clinic for treatment He was reexamined in that department a few days later and once more the lungs and heart were found to be normal

On June 8, 1933, the patient entered the hospital complaining of pain in the chest which had come on the previous day He was in the hospital for one month with a characteristic mild attack of lobar pneumonia involving the left lower lobe and due to the pneumococcus Type IV Throughout the period of his stay in the hospital the heart was totally irregular He had been a patient at Mercy Hospital in December 1932 A letter from that hospital states that he had had lobar pneumonia of the left lower lobe At that time also the heart was fibrillating The cause for the auricular fibrillation gave rise to much speculation Some thought that in spite of the fact that the heart was little if any enlarged and the sounds perfectly clear, that he might have rheumatic mitral valve disease However, opinions favored the view that the disturbance of rhythm was associated with arteriosclerotic heart disease

The patient was admitted to the hospital again on January 2, 1934 After his discharge on July 8, 1933, he was reasonably well but he did not feel as well as he had before He came to the Syphilis Clinic from time to time where he was treated for the luetic infection Off and on he worked at odd jobs but felt unable to work regularly There was some shortness of breath on exertion During this period physical examination and roentgenograms demonstrated the persistence of infection in the lower lobe of the left lung One week before the second admission to the hospital, while working in the market moving heavy barrels, he was suddenly taken with severe pain in the interscapular area The pain was so intense that he had to stop work and go home He began to cough, the cough was worse at night and he was unable to sleep on account of the severity of the pain He grew more and more short of breath Two days before entering the hospital the pain shifted from the back to the front of the chest and was particularly severe over the lower end of the sternum The pain, he said, was exceedingly sharp, as severe as a *gothache*

Examination Temperature 100.2° F, pulse 104, respirations 24, blood pressure 108 systolic and 54 diastolic

The patient was propped up in bed complaining of severe pain about the heart. He was a short man, a typical chondrodystrophic dwarf. His pain seemed to be quite severe. There was only a moderate degree of dyspnea. Over the left shoulder was the scar of a stab wound received years before. The eyes were normally prominent. The pupils were a little irregular and constricted due to the administration of morphia. Later examinations demonstrated that they reacted actively to light and on accommodation. The eye movements were normal. The fundi showed a moderate degree of arteriosclerosis. In the left eye there was partial detachment of the retina. Many teeth had been extracted, those remaining were in poor condition. The throat showed nothing remarkable. There was no enlargement of the superficial lymph nodes. The thyroid was not enlarged. Over the lower lobe of the left lung the percussion note was impaired, the breath sounds were enfeebled, and a small number of scattered rales were heard after cough. The heart was enlarged. Cardiac dullness measured 5 cm. to the right and 12 cm. to the left of the midline. The apex beat was easily felt. The heart sounds were clear, the second pulmonic louder than the second aortic. A loud pericardial friction rub was heard over the heart, loudest in the fourth interspace. The area of dullness over the manubrium was somewhat increased. The rhythm was totally irregular. The peripheral vessels showed a moderate degree of arteriosclerosis. The abdomen was normal in appearance. No masses were felt. The liver and spleen were not enlarged. The genitalia showed nothing abnormal. There was no edema. The neurological examination was negative.

In this patient the situation was confusing. He had been fibrillating for over a year and it was assumed that he had arteriosclerotic heart disease. The sudden onset of pain followed by fever, leukocytosis, the symptoms of myocardial insufficiency and a pericardial friction suggested that he might have coronary occlusion. After a few days the signs of pericardial effusion developed and aspiration yielded a purulent fluid from which pneumococcus Type IV was cultivated. The pericardial sac was opened and drained. For a while the patient improved but later grew worse again and died two months after entering the hospital.

The anatomical diagnosis reads: History of pneumonia followed by pericarditis, dense pleural adhesions, left lower lobe, adherent thickened pericardium with drained walled-off pericarditis, mycotic aneurysm of arch of aorta extending into pericardium, generalized pleural adhesions, hypertrophy of right ventricle, chronic passive congestion of viscera, thrombosis in old caseous primary focus, right lower lobe, encapsulated caseous area in peribronchial nodes.

In both of these patients a very loud pericardial friction was heard over the whole heart. This is precisely what is usually heard with pericarditis and it is an important point distinguishing it from coronary occlusion. When a pericardial friction appears over an infarcted area of heart muscle it is a faint rub often difficult to hear, well localized and transient. I have never heard a diffuse, loud friction with coronary occlusion.

III PULMONARY EMBOLISM

In 1927 I published an article calling attention to the very great importance of embolic phenomena in the diagnosis of coronary occlusion.

I pointed out that pulmonary embolism occurred frequently and cited an instance illustrating how very, very difficult it may be to distinguish between coronary occlusion and pulmonary embolism. On account of its great interest in this connection I report the case again.

CASE III

A woman, 69 years of age, was operated upon by Dr. E. H. Richardson at the Hospital for the Women of Maryland and a perineal repair performed. She had been carefully examined a few weeks before by Dr. H. M. Thomas, Jr., who found no important abnormality, except that the blood pressure was systolic 160 mm Hg and diastolic 80 mm Hg. After the operation, convalescence progressed uneventfully, and on the twelfth day the patient was out of bed. On the evening of the fifteenth day, while walking about the corridor, she suddenly had a feeling of faintness and would have fallen had she not been supported by a nurse. When she had been gotten to bed she complained of a feeling of pressure over the chest and difficulty in getting her breath. The following morning she still complained of constriction in the chest and shortness of breath.

The blood pressure was much lower than it had been before operation, but no estimate had been made after operation. The pulse rate, previously around 80, rose to 100 and over and remained thereabout. The heart was a little further out to the left. The patient had a grayish, slightly cyanotic color, was deeply prostrated, and gave one the impression of being seriously ill. The following afternoon a definite coarse, to-and-fro pericardial friction was heard over the sternum and to the left of it, which disappeared after six or eight hours and did not return. The lungs remained clear except for a few râles at the base, and there was no cough and no bloody expectoration.

For a week or longer the patient remained prostrated, was delirious and displayed Cheyne-Stokes breathing. On the twenty-seventh day after operation, swelling of the left leg with pain in the groin pointed clearly to thrombosis of the left femoral vein. The swelling of the leg subsided, the delirium cleared, the pulse slowed and the patient gradually improved. In September she was out of bed and she left the hospital September 24 in good condition.

At the time I thought the patient had had coronary occlusion but even then I was perplexed and uncertain, as shown by the comments I added. "It was my own belief, shared by Dr. Thomas, that the patient had had a coronary occlusion. The character of the attack, the appearance of the patient, the rapid pulse, the fall in blood pressure, the pericardial friction together make a convincing picture. Hearing about the illness without an opportunity to see the patient, one might well argue for pulmonary embolism. The time after the operation, the sudden onset, the symptoms of shock, the left femoral thrombosis, all strongly suggest pulmonary embolism. It might even be suggested that the rub heard over the heart may have been a pleuro-pericardial friction. I am convinced it was not. However, it is not my intention to argue the point but rather to illustrate how difficult at times the diagnosis may be."

It is certainly true that the symptoms and the course of events during the illness were typically characteristic of postoperative thrombophlebitis with pulmonary embolism and no other diagnosis would have been considered.

had it not been for the presence of a pericardial friction Does the appearance of a pericardial friction make it necessary to abandon the diagnosis of pulmonary embolism with infarction when all the other symptoms are typical of the condition? This question troubled me continuously until the observation of a second somewhat similar instance convinced me that a loud pericardial friction may occur with infarction of the lower lobe of the left lung under circumstances when the possibility of the occurrence of coronary occlusion is very remote, if not indeed beyond all reasonable expectation

I shall not now pause to discuss whether the pericardial friction was an endopericardial or an extrapericardial rub It seems to me likely that it was extrapericardial All I can say with certainty is that it was a very loud to-and-fro friction and that from the character of the sounds it was impossible to decide whether it was endo- or extrapericardial The main facts about this second case are as follows

CASE IV

A clergyman, 43 years of age, entered the Bon Secours Hospital under the care of Dr E D Freeman, on May 5, 1932 During the previous year and a half he had had recurring attacks of severe upper abdominal pain which Dr Freeman diagnosed gall-stone colic Under conservative treatment there was no improvement, indeed, the attacks became more frequent and more severe The patient was a rather obese man, in good general condition, who showed no abnormality on physical examination other than tenderness in the epigastrium and in the gall-bladder area The blood pressure was 132 systolic and 78 diastolic On May 19, 1932, the patient was operated upon by Dr E H Hayward and the gall-bladder removed The diagnosis made at operation was chronic perforation of the gall-bladder, chronic cholecystitis and hepatitis adjacent to the gall-bladder Dr H S Everett examined the tissues removed at operation and reported subacute cholecystitis and cholelithiasis

During the first week after operation the patient progressed satisfactorily From time to time he had a little asthmatic wheezing He had had asthma since 16 years of age, particularly in the spring and early fall Everything went well until the morning of May 25 when he was suddenly taken with severe pain in the left axilla and left shoulder The temperature which during the previous week had fluctuated between 98° and 100° rose to 102° and the pulse rate to 120 Later on the same day a pleural friction rub was heard in the left axillary area The patient was somewhat shocked and a little cyanotic The following four or five days he had cough with frankly bloody expectoration The symptoms were very characteristic of pulmonary embolism and this diagnosis was made The patient then steadily improved during the week until June 2 On that day when turning on the left side, he suddenly went into a condition of collapse There was great shortness of breath, he became pale and cyanotic and the pulse rate rose to 130 The following morning a loud to-and-fro friction was heard all over the heart The manifestations on this occasion, though somewhat more severe, were exactly like those which had occurred a week before, except that there was no pain and the symptoms of collapse were followed by the appearance of a loud pericardial friction The presence of the precordial friction led to the suspicion that this attack might be one of coronary occlusion With this diagnosis in mind, Dr Freeman asked me to see the patient

At the time of my visit, which was about 32 hours after the onset of the symptoms of collapse, the patient still was very ill, he was propped up in bed quite dyspneic, very pale, somewhat cyanotic and sweating profusely It was impossible

to make a thorough examination. However, there were definite signs of consolidation in the left axilla and in this area also a pleural friction. All over the heart there was a loud grating to-and-fro friction. There was no variation in the intensity of the rub with inspiration. The pulse was rapid, of small excursion and the pressure was low.

From then on the patient steadily improved. At the end of four days the pericardial rub had disappeared and after that he made a slow but otherwise uneventful recovery. He left the hospital on July 5, 1932.

After leaving the hospital when he began to walk about he noticed that there was some swelling of the left calf, the left calf measured two or three centimeters more than the right calf. He wore a pressure bandage and the swelling soon disappeared.

On March 3, 1934, I had an opportunity to examine the patient again. He said he had been perfectly well since leaving the hospital and had had no symptoms except a little irritation in the throat and a little wheezy cough from time to time. These asthmatic symptoms, however, had been much less severe than they had been in former years. There had been no symptoms whatsoever referable to the heart or circulation. No pain about the heart, no palpitation, no shortness of breath, no symptoms which might to the slightest degree suggest angina pectoris. The examination on this occasion was entirely negative except that the patient had gained some weight and was moderately obese. The notes of the examination are as follows:

Examination Temperature 98.2° F, pulse 72, respirations 16, blood pressure 132 systolic and 80 diastolic. Weight 188 pounds. Height 5 ft 7¼ inches.

The patient is somewhat obese, 32 pounds above the average weight for his height and age. He has a good color and a healthy appearance. He is a mouth-breather. The eyes are normally prominent, pupils equal, react actively, eye movements are all normal. The teeth are in good condition. The tongue is clean. The throat shows no abnormality. There is no enlargement of the superficial lymph nodes. The thyroid is just felt, average size, symmetrical, no nodules. The chest is well formed and symmetrical, with a wide costal angle. Movements are equal on the two sides. The lungs are perfectly clear except for a slight degree of emphysema. The apex beat of the heart is a barely visible impulse in the fifth interspace inside the nipple line. The area of cardiac dullness is not enlarged. There is no impairment over the manubrium. Heart sounds are clear and of normal quality. Pulse is regular, the peripheral vessels not thickened. The abdomen is normal in appearance. In the right upper quadrant is the scar of the operation wound. There is a fairly thick panniculus. No tenderness. No masses are felt. The liver and spleen are not enlarged. There is a little prominence of some of the superficial veins about the left ankle. At the present time no swelling of the left leg. The measurements about the calves are 38 cm. on each leg.

IV RUPTURE OF THE AORTA

When this Society met at Baltimore two years ago I demonstrated at Ward Rounds a patient showing all of the classical manifestations of coronary occlusion. The following day a distinguished Visiting Physician selected the patient to illustrate his remarks upon the same subject. At the time no one doubted the accuracy of the diagnosis. I shall briefly state the main facts about the case and tell the subsequent developments.

CASE V

A white married housewife 63 years of age, was admitted to The Johns Hopkins Hospital on November 27, 1930, complaining of intense pain under the sternum and

shortness of breath For four or five years she had had dyspnea on exertion and occasionally a feeling of substernal pressure with dyspnea which would pass after a short period of rest Two days before admission, while varnishing a piece of furniture, she suddenly was seized with intense pain in the region of the heart She described this sensation saying it felt "as though the insides were being torn out" again "as though there were an expanding ball inside the chest about to burst," and yet again "as though she had been hit by a sledge hammer" She fell back dazed, perhaps even unconscious, and was carried to bed The pain continued, not so severe as at first, but still very severe, and a hypodermic injection administered by a physician gave but little relief She vomited a number of times and had some cough with slightly blood-streaked expectoration She was brought to the hospital 53 hours after the onset of symptoms

Examination Temperature 102° F, pulse 108, respirations 34, blood pressure 210 systolic and 140 diastolic

The patient was a rather obese woman, highly flushed, breathing rapidly and complaining of substernal pain There was moderate cyanosis The eyes were normally prominent, pupils equal, reacted actively The eye grounds showed moderate arteriosclerotic changes The teeth had been extracted and she wore a complete double denture No enlargement of the superficial lymph nodes The thyroid was not enlarged The lungs showed no abnormality other than the presence of numerous moist râles over both lower lobes The heart was enlarged, sounds much enfeebled There was a faint systolic murmur at the apex The sounds at the base could scarcely be heard The pulse was regular except for an occasional extrasystole The abdomen was soft and relaxed No tenderness Liver and spleen not enlarged Slight pitting edema over the shins The pelvic and rectal examinations revealed nothing abnormal

Course During First Stay in the Hospital The patient was given morphia, was then bled and digitalis started She continued to have severe attacks of substernal pain The blood pressure, which on admission was 210 systolic and 140 diastolic, fell rapidly to 110 systolic and 78 diastolic then slowly rose again during the following twelve hours to 180 systolic and 70 diastolic The temperature was 99° the following day and thereafter only occasionally a little elevated The leukocytes varied from 9,000 to 16,000 during the first week The patient's general condition, which was desperate on admission, improved a little but she continued to be miserable, with frequent attacks of substernal pain and severe attacks of coughing associated with urgent dyspnea The pulse, regular on admission, was totally irregular the following day and fibrillation continued from that time Paravertebral injections of the sympathetic ramus somewhat relieved the pain but did not abolish it The physical examination showed but little change during the period of her stay in the hospital The heart sounds became more forcible There was a great deal of discussion about a diastolic murmur, which some heard but which others could not hear Sometimes this murmur was heard only at the apex, at other times faintly to the left of the sternum The patient left the hospital April 15, 1931, still in a rather miserable and unsatisfactory state

Interval Note At home she was always miserable She could make no effort and only with assistance could take a few steps from chair to chair On July 6, 1931, she was seen in the Dispensary when she was very short of breath and cyanotic Examination otherwise did not differ from what had been found when she was in the hospital Later in July she began to have still more severe attacks of pain and the cough became more troublesome In October she began to have a different type of pain from that which she had had before This consisted of attacks of severe, sharp pain in the epigastrium, and from then on this symptom remained more prominent than any other Patient was admitted to the hospital again on November 20, 1931

Examination Temperature 99.4° F, pulse 88, respirations 26, blood pressure 150 systolic and 95 diastolic

The patient was propped up in bed, with marked dyspnea. Evidently she had lost a great deal of weight. There was moderate cyanosis. She complained bitterly of severe pain about the heart and gnawing pain in the epigastrium. Occasional attacks of cough occurred with severe dyspnea. The face was quite drawn and contracted with pain. Skin and mucous membranes had a fairly good color. The eyes showed nothing abnormal. There was no enlargement of the superficial lymph nodes. The thyroid was not enlarged. The lungs were clear except for numerous moist râles over both lower lobes and a few scattered sonorous râles. The heart was enlarged, the area of dullness measuring 5 cm. to the right and 12 cm. to left of the midline. At the apex the first sound was loud and booming and was followed by a loud, blowing systolic murmur. In the aortic area there was a rough systolic murmur, and the aortic second sound was accentuated and somewhat ringing in quality. The pulse was totally irregular, peripheral vessels thickened and tortuous. The abdomen was soft and relaxed. Marked tenderness was present in the epigastrium, particularly over the aorta. The aorta could easily be felt. It seemed to be wider than normal and to pulsate violently. No clubbing of the fingers was noted and no edema of the legs. The neurological examination was negative.

Course After admission the patient improved very little. She was constantly most miserable, with substernal pain, attacks of coughing with intense dyspnea, and complaining always of a severe gnawing pain in the epigastrium which varied a good deal in intensity. In some of the attacks of dyspnea there was wheezing. Everyone agreed that the abdominal aorta was dilated and tender and some thought there was a fusiform dilatation. On this admission, as on the first, there was a dispute about a diastolic murmur. At times the patient was delirious. On February 22 she contracted the respiratory infection then prevalent on the Ward. She developed bronchopneumonia and on February 27, 1932, was released by death from all her misery and suffering.

The blood count demonstrated a mild secondary anemia. The Wassermann reaction on the blood serum was negative. The urine contained albumin and a few casts. The temperature on the first admission was 102°, it fell rapidly to normal and thereafter varied at first from 97° to 99°, occasionally going to 100°. During the second admission it varied from 97.6° to 100°. Later it fell to normal and with the terminal pneumonia rose and varied from 99.6° to 104°.

Many electrocardiograms were taken. In all there was evidence of myocardial disease but the curves did not show the changes characteristic of coronary occlusion.

Roentgenograms showed enlargement of the heart and aorta. The measurements of the teleroentgenogram were M R 6, M L 10.4, T 27.2.

The anatomical diagnosis reads Arterio- and arteriolosclerosis, scarring of kidneys, atrophy of acinar tissues of pancreas, history of hypertension and auricular fibrillation, cardiac hypertrophy and dilatation, focal necroses and scars in myocardium, chronic passive congestion of viscera, bilateral hydrothorax, subcutaneous edema, dissecting aneurysm of aorta and iliac arteries, saccular aneurysm of dissecting aneurysm, fibrous adhesions between right auricle, arch of the aorta and pericardium, chronic bronchitis and tracheitis, emphysema, lobular pneumonia, chronic cervicitis and retention cysts in uterus, myomata and polypi uteri, secondary anemia, hyperplasia of bone-marrow.

During the past three years I have encountered seven instances of rupture of the aorta at clinical pathological conferences. In all seven the diagnosis of coronary occlusion had been made when the patient first entered the hospital but in five it was changed to rupture of the aorta before

the autopsy findings were disclosed. When the patient dies shortly after the accident occurs the distinction between the two may be very difficult as the following case illustrates.

CASE VI

A white man, 79 years of age, was brought to The Johns Hopkins Hospital on November 12, 1929, in an unconscious state. He had always been in remarkably good health except that for some time he had been somewhat short of breath on exertion and occasionally had had a little substernal pain especially at night. About 10 o'clock on the morning of November 12 as he was riding home from work on the street car, he was suddenly seized with severe pain under the sternum. He became very dizzy and lost consciousness. He was picked up by the police and brought to the hospital. In the accident room he regained consciousness and could only state that he had had a very severe pain and had then lost consciousness. He was obviously deeply shocked and quite ill. He was a little short of breath, the hands and feet were cold, there was marked cyanosis and the pulse was imperceptible. The blood pressure could not be taken by auscultation, by palpation the systolic pressure was 58 mm Hg. He was at once admitted to the Ward.

Examination Temperature 98.7° F, pulse 76, respirations 24.

The patient was an old man with marked arteriosclerosis of the peripheral and retinal vessels. Respirations were somewhat labored. He complained of a dull aching under the sternum. The chest was narrow and thin, disproportionately wide antero-posteriorly. The lungs showed nothing remarkable except a few râles at the bases. The heart was somewhat enlarged, the area of dullness measuring 4 cm to the right and 11½ cm to the left of the midline. The apex impulse was in the seventh interspace, the action irregular due to the occurrence of numerous extrasystoles. The first sound at the apex was followed by a short systolic murmur. The sounds were feeble and could not be heard at the base. The abdomen showed nothing remarkable except that the liver was felt 5 cm below the costal margin.

Course in the Hospital After stimulation, the patient's condition at first improved somewhat. The blood pressure in the right arm rose to 174 systolic and 130 diastolic. The pulse was never more than vaguely perceptible. Following the accident he remained anuric for 30 hours.

Two days after admission he suddenly developed abdominal distention, complained of abdominal pain and soon afterward died, apparently of cardiac failure. Shortly before death there was a little dullness at the right base suggesting the presence of a patch of pneumonia.

Laboratory Examinations Blood count Hemoglobin 74 per cent, red blood corpuscles 3,740,000, leukocytes 11,560.

The leukocytes varied from 12,000 to 18,000. The Wassermann reaction on the blood serum was negative. The urine showed an abundance of albumin with many hyaline and granular casts. The nonprotein nitrogen and uric acid of the blood were at a normal level. The temperature on admission was normal and then gradually rose, varying irregularly between 99° and 101°.

Roentgenogram of the chest showed a soft infiltration at both apices, tuberculous in character. Electrocardiogram, rate approximately 94. Rhythm totally irregular. Slurring of R-waves in all leads, low voltage in all leads.

The anatomical diagnosis reads: Dissecting aneurysm of ascending aorta with rupture into pericardium, hemopericardium, arteriosclerosis, emphysema, bilateral multilocular hydrocele, thickening of splenic capsule, diverticulum of duodenum, minute abscess of liver.

In distinguishing between coronary occlusion and rupture of the aorta too much reliance must not be put upon the electrocardiogram. A man, 45 years of age, was suddenly seized while eating his mid-day meal with excruciating pain in the chest radiating to the left shoulder. He died at the end of 24 hours and the autopsy revealed rupture of the aorta with the formation of a dissecting aneurysm. The electrocardiographic report reads as follows: P-waves of low voltage. QRS slightly slurred. Q-waves prominent in Lead III. T-waves inverted in Lead I, diphasic and of low voltage in Lead II, upright in Lead III.

Comment Record suggests coronary artery disease.

V INTERSTITIAL EMPHYSEMA OF THE LUNGS

CASE VII

On February 12, 1933, I saw at Washington with Dr. W. C. Moore and Dr. J. W. Esler, a physician, 51 years of age, who had previously enjoyed excellent health. On the morning of February 8 while shaving he was suddenly seized with intense pain in the region of the heart radiating to the left shoulder. The pain lasted about half an hour and then gradually passed. When Dr. Moore examined him two hours later no definite abnormality was found. The heart and lungs were quite normal. The temperature was 98°, pulse 54 and regular, respirations 20, blood pressure, systolic 110 and diastolic 80. The following day an electrocardiogram was reported by Dr. Esler as follows: Regular rhythm, rate 60, T-waves upright in all leads, conduction interval normal, maximum QRS potential 9 mm. The blood count was normal, the leukocytes 8,550 per cubic mm. On the morning of February 11 the patient reported to Dr. Moore that during the night when lying on the left side he had heard a curious loud bubbling, crackling sound synchronous with the heart beat. His wife sitting on the bed beside him could easily hear the sound. At this time Dr. Moore could make out no abnormality whatsoever on physical examination. The heart and lungs were quite normal. The temperature was 98°, pulse 66, respirations 20, blood pressure, systolic 100, diastolic 75.

Later in the day Dr. Esler thought he heard a pericardial friction. This seemed to establish the diagnosis of coronary occlusion which had previously been suggested. When I saw the patient on the afternoon of the following day he was sitting up in bed laughing and talking, protesting that he felt perfectly well. He certainly was in good spirits and had every appearance of robust health. The temperature, pulse, respirations and blood pressure were all normal as they had been before. I examined the heart and the lungs with the greatest care and could detect nothing that was to the least degree abnormal. When I expressed surprise the patient laughingly said that he could easily produce the sound. He turned on his left side, shifted about a few moments and suddenly said, "There it is." I put my stethoscope over the apex beat of the heart and with each impulse heard the most amazing sound. It is difficult to describe. Crunching is the best adjective I can think of though it is far from apt especially since crunching has been widely used to describe pleural friction to which it bore no resemblance. It certainly conveyed the impression of air being churned or squeezed about in the tissues. It recalled an instance of pneumopericardium I had listened to years before. When the patient turned on his back the sound at once disappeared. The possibility of pneumothorax came to my mind. However, a second thorough examination of the lungs was quite negative. Still I persisted and suggested that it might be a small localized pneumothorax near the apex of the heart. The following day a roentgenogram was taken with a portable machine by Dr. E. M.

McPeak Dr McPeak's report reads as follows "Examination of the chest shows the bony thorax, heart and great vessels normal in appearance There is slight thickening of the interlobar pleura on the right side with some slight increase in density throughout the right base The appearance in the right base is probably due to bronchiectasis There is no other evidence of abnormality except perhaps a very slight widening of the aortic arch and the thoracic aorta"

The extraordinary sound disappeared after a few days At the end of two weeks the patient was up and about and during the past year has led an active life and has had no symptoms of ill health Dr Moore examined him on February 20, 1934, and found him in excellent condition

The course of events in this patient convinced me that he did not have coronary occlusion and yet I could not clearly understand what had caused the sudden pain and how the extraordinary sound heard over the heart had been produced I revolved the matter in my mind again and again until four months later when I saw in the wards of The Johns Hopkins Hospital a boy with subcutaneous emphysema in the neck and emphysema of the mediastinal tissues The moment I put my stethoscope over his heart it flashed upon me that here was the explanation for the puzzling sound I had heard over the heart of the Washington physician I add a brief account of the illness of this patient

CASE VIII

A white boy, 17 years of age, a tin worker, was admitted to The Johns Hopkins Hospital June 25, 1933, complaining of pain on breathing Though a delicate lad, he had previously always been well On the day before admission at 6 p m, while sitting quietly on a chair, he suddenly had a feeling of pressure under the sternum as though there were a lump there Soon swelling actually appeared above the clavicles and he had severe pain on breathing deeply, on swallowing and on turning the head He was seen in the accident room a few hours after the symptoms came on Examination of the throat and larynx revealed no abnormality There was subcutaneous emphysema of the tissues in the neck and over the upper part of the chest During the night he was very uncomfortable with pain under the sternum especially on deep breathing and swallowing He spent most of the night sitting up The next morning he entered the hospital

Examination Temperature 101.2° F, pulse 86, respirations 24, blood pressure 110 systolic and 70 diastolic

A thin, pale, undernourished boy lying quietly in bed complaining of pain under the sternum and about the neck He was mildly apprehensive There was subcutaneous crepitation over the front of the neck which extended backward to the trapezius muscle on both sides and downward over the clavicles to about the second rib on the left and the nipple on the right

The eyes were normally prominent, the pupils equal and reacted actively to light Extraocular movements were normal Slight enlargement of the superficial lymph nodes in neck, axillae and groins was present The thyroid was not enlarged The chest was long and thin with a narrow costal angle The sternum was prominent, producing a slight degree of pigeon breast The lungs were clear The apex beat of the heart was in the fifth interspace 6 cm to the left of the mid-line The sounds were distant, barely audible They were obscured by a loud systolic crunching sound heard all over the heart and in the left interscapular area behind The abdomen was normal in appearance Walls soft and relaxed No tenderness No mass Liver and spleen not enlarged Right kidney easily felt Reflexes normally active

Course after Admission to the Hospital The temperature which was 101.2° on admission gradually fell and after the third day was normal. The symptoms all soon subsided and the subcutaneous emphysema and curious sound over the heart disappeared. He left the hospital well 20 days after admission. On July 31, 1933, he reported at the Out-Patient Clinic. He was feeling perfectly well and the physical examination was quite negative.

Laboratory Examinations Blood hemoglobin 105 per cent, red blood cells 5,240,000, leukocytes 13,000

Wassermann reaction (blood), negative

Roentgenogram 6/26/33 Chest subcutaneous emphysema Free air in the tissues of the neck and trachea, free air in the mediastinum

7/5/33 Lungs clear

Urine Specific gravity 1.018, no albumin, no sugar, a few leukocytes in the sediment

It might be objected in this instance that the peculiar sounds heard over the heart may have been due to the pressure of the stethoscope upon air in the subcutaneous tissue of the chest wall since crepitus was felt below the left clavicle. However, I am convinced that the sounds could not have been produced in this way because they occurred only with each contraction of the heart. In the following case this possibility was entirely excluded as there was no subcutaneous emphysema of the chest wall.

CASE IX

A white maid, 24 years of age, came to the Out-Patient Department of The Johns Hopkins Hospital, May 31, 1930, complaining of pain in the abdomen and chest. She was examined first in the Gynecological Clinic where no important abnormality of the pelvic organs was discovered. She spoke of having spat blood now and again over a period of years. Examination in the Medical Clinic was quite negative. There was no abnormality about the heart or lungs and a roentgenogram of the chest showed the lungs to be clear. She was then referred to the Laryngological Clinic where infection of the left antrum was found. From then on she was treated in this clinic at intervals for years. The antrum was irrigated on a number of occasions. On June 18, 1931, the left ethmoidal cells were opened and drained. Five days later a radical operation was performed upon the left antrum. She recovered satisfactorily from the operations but continued to have headaches, unpleasant symptoms of nasal occlusion and a profuse purulent discharge. On the morning of July 17, 1933, the left antrum was irrigated. In the afternoon the left side of the face began to swell and the pain became more and more severe. In the evening the following note was made by Dr. James Bordley, Jr.: "Following irrigation of the left maxillary sinus the patient developed emphysema of the cheek. Late this evening she began to complain of pain about the heart accentuated by respiration. At present she is quite uncomfortable. Every now and then she sits forward with the hand pressed over the heart complaining of severe pain. When asked to localize the pain she places the finger just to the left of the sternum at the level of the sixth and seventh costal cartilages. There is no respiratory difficulty, no cyanosis, and no pain in the left shoulder or arm. Subcutaneous emphysema of left side of face is present and subcutaneous crackles extend down to the clavicles on both sides of neck. No emphysema is noted over the chest or in axillae. On auscultation over the heart there are numerous popping and crackling sounds which vary with the cardiac cycle and with respiration. The heart sounds are somewhat distant especially at the base of the heart. There is a resonant note over the manubrium. The lungs are clear. There is no evidence of pneumothorax. Impression: Emphysema of face, neck and mediastinum."

After four days the emphysema had completely disappeared and the patient was as well as before. There was slight fever during the attack, 98.6° to 100° . Leukocytes were 10,462.

Listening to a description of these episodes it may appear far fetched to say that they resemble the manifestations of coronary occlusion. However, under certain circumstances the resemblance may be very close. Not, it is true, when there is subcutaneous emphysema, but if the air escapes into the interstitial fibrous bands of the lung and travels only to the mediastinum then the similarity may be very confusing. With the escape of air and the tearing apart of the fibrous tissue there is sudden severe pain. This may be followed by fever and a slight leukocytosis. The systolic crunching sound which is heard over the heart may easily be mistaken for a pericardial friction. If the observer is not familiar with the peculiar symptoms which accompany this accident, coronary occlusion may be erroneously diagnosed.

HEPATIC FUNCTION IN RELATION TO HEPATIC PATHOLOGY EXPERIMENTAL OBSERVATIONS^{*}

By FRANK C MANN, M D , *Rochester, Minnesota*

It is the ideal and ambition of the investigator in experimental medicine to discover new facts by the experimental method in order to aid the clinician in his work of preventing disease and healing the sick. While I would object strenuously to the viewpoint that all experimental research should be practical in nature or have a practical aspect, because it is not possible to evaluate research in terms of practical application, nevertheless the experimental investigator with a clinical point of view strives to undertake to investigate those problems in which the answer may ultimately benefit the patient. This was the object which my associates and I had in mind when we undertook a series of investigations on the functions and experimental pathology of the liver. The results of our investigations have only partially fulfilled our hopes and must be considered at present as having accomplished little more than preparation for what we hope will be more fruitful investigations. A general review only will be presented since the scope of our subject is broad and the number of investigations we have made on it numerous.

The liver has many definite and important known functions. Knowledge of the physiologic activity of the liver, even though this activity is vital and manifold, has not been of great value to clinical medicine owing mainly to a lack of knowledge of how the hepatic functions are affected by pathologic changes in the organ. From the experimental standpoint, therefore, the next step, after determining some of the functions of the liver, was to investigate the effect of hepatic injury on these functions. This necessitated the experimental production of pathologic lesions of the liver and their study.

Many methods have been used to produce pathologic changes in the liver and to decrease hepatic function. These include (1) employment of the more or less specific hepatic poisons, as chloroform, phosphorus, carbon tetrachloride, and so forth, (2) partial removal of the organ, (3) obstruction of the biliary outflow, (4) shunting of the portal blood away from the organ, and other less used methods.

One fundamental characteristic of the liver usually has been responsible for defeating the purpose of most of the experiments performed in order to reduce the functional capacity of the liver. Restoration to some extent occurs in most organs of the body after partial removal or injury. It occurs to a very remarkable extent in the liver. This characteristic of the liver makes it difficult to produce experimentally a decrease in the functioning

^{*} Read at the Chicago meeting of the American College of Physicians, April 16, 1934
From the Division of Experimental Medicine, The Mayo Clinic

hepatic tissue to such an extent that the hope would be justified that the physiologic activity had been reduced to an amount that could be measured

The effect of hepatic poisons on the liver is usually transitory, and if the animal recovers from the acute effects of the drug, the hepatic parenchyma is restored to almost its normal condition. It is only by repeated administration of such substances that a more permanent pathologic change can be made in the liver. Although there are many substances which will produce a more or less specific hepatic injury, for purposes of experimental investigation carbon tetrachloride is the best so far discovered. As was shown by Lamson¹⁸ and his associates, repeated administration of this substance in appropriate doses for several weeks produces a condition of the liver similar to cirrhosis as seen in man.

Partial removal of the liver, from individuals of those species of animals in which removal is anatomically possible, produces a decrease in hepatic tissue but not for a very long time. Restoration of the normal organ, even after as much as 70 per cent has been removed, is usually rapid and complete^{14, 17}

Obstruction of the biliary outflow injures one function of the liver, that of secreting bile, but does not greatly interfere with the other hepatic functions or greatly injure the hepatic parenchyma unless the obstruction is maintained for several months. By that time the effect of the obstruction itself on the other tissues of the body is so great that it is hazardous to interpret the results of functional studies in terms of hepatic injury.

The shunting of the portal blood from the liver by an Eck fistula produces within a few weeks a decrease in the size of the liver by about one-half. This atrophy, however, usually is not of sufficient magnitude to be of value for studies of hepatic insufficiency. Our studies on animals with an Eck fistula have been disappointing.

We have found that a combination of these various methods furnishes a preparation in which functional hepatic tissue is permanently decreased. We discovered that restoration of the liver after partial removal either did not occur, or only to a limited extent, if (1) the portal blood was shunted away from the organ, (2) if biliary obstruction was present, or (3) if cirrhosis existed. If any one of these procedures was carried out, that is, making an Eck fistula, obstructing the common bile duct, or producing cirrhosis, and if a portion of the liver subsequently was removed, a definite and permanent decrease in hepatic tissue was secured²². It was sometimes possible to decrease the hepatic tissue to 15 per cent or less of the normal amount. The results of the investigation which we wish to report were secured from observations made in part on animals from which the liver had been totally removed, partially removed, injured transitorily with chloroform or phosphorus, or made cirrhotic with carbon tetrachloride. Other observations were made on animals from which the liver had been partially removed after an Eck fistula had been made, after obstruction of the biliary outflow, or after the development of cirrhosis.

In attempting to evaluate methods for estimating hepatic function, several facts concerning the functional characteristics of the liver should be constantly kept in mind (1) The capacity of the normal liver to carry on its many functions is greatly in excess of the normal needs of the organism. Although this statement is probably true of all organs of the body, it is particularly applicable to the liver. It would thus seem to be extremely difficult ever to measure the capacity of the normal liver in regard to any one of its functions without producing a very abnormal physiologic condition. (2) The capacity of the liver to perform its functions is dependent on many factors, and may change with extreme rapidity. Determination of a specific hepatic function of a particular animal at a definite time, even if it could be made with reasonable accuracy, would not necessarily be the same after a very short period of time. (3) A decrease in one of the functions of the liver does not necessarily mean that all functions, or any other one of its many functions, are equally impaired or even at all injured. There seems to be a dissociation of functions of the liver, so that it is possible for one to be defective in an otherwise normally functioning organ. (4) Most of the functions of the liver are so intimately associated and correlated with the physiologic activity of other organs or tissues that it is difficult or impossible definitely to delineate the hepatic factor. Hepatic activity is often only a part, although important and often vital, of a physiologic process in which one other organ or tissue, or more than one, is involved. (5) Finally it should be noted that the liver maintains all its known and therefore its possible measurable functions with extreme stubbornness. Normal hepatic functions are carried on by a very small amount of functioning tissue. An animal without a liver may be totally unable to maintain a certain physiologic process, while an animal with only a small percentage of its normal amount of hepatic tissue seemingly may function as well in this respect as when all its liver was present.

STUDIES OF THE BILE AND ITS CONSTITUENTS

The function of the liver which in the past has been of most interest to the clinician is secretion of bile. This is owing to the fact that the bile contains a pigment which, when retained in the body, excreted in the urine, or prevented from reaching the digestive tract, furnishes definite evidence to the clinician that something may be wrong with the function of the liver or the discharge of its external secretion. Study of this secretion is handicapped by the fact that it is poured into the intestine and is not readily accessible for observation. It has been necessary, in order to overcome this difficulty, to study the more important constituents of bile as they may be retained in the body or appear in the urine.

The bile contains several substances, three of which appear to be the most important: cholesterol, bilirubin, and bile acids. Too little is known at present in regard to cholesterol, either its origin or significance in the bile.

to justify a consideration of it as a possible indication of hepatic function even if it were possible to obtain the bile directly and to estimate the cholesterol quantitatively. Bilirubin and the bile salts have been important substances in the search for a method of estimating hepatic function.

Because jaundice was the first clinical sign observed of hepatic dysfunction, bilirubin has been in the past, and still is probably, the most important substance used to indicate hepatic injury. Physiologically several important facts are known concerning bilirubin which have important bearings on its employment as an indicator of hepatic function. These facts are (1) bilirubin is formed from hemoglobin²⁶, (2) a considerable portion of the bilirubin found in the bile is formed outside the liver^{21, 23, 24, 25}, (3) only a small portion of the normal liver is necessary to excrete all the bilirubin formed in the body²⁰, (4) only bilirubin which has reached the hepatic cells gives the so-called direct van den Bergh reaction⁷. Although satisfactory methods have been developed for estimating the amount of bilirubin retained in the blood, such as the van den Bergh method¹ and the icteric index,³⁰ and though the data so secured may be of great clinical value, the facts mentioned definitely indicate that such data do not suffice for quantitating hepatic injury, as the amount of bilirubin formed and the rate at which it forms depend on several factors, many of which determine or change the rate of formation of bilirubin and the amount of this substance formed. Probably the most important of these, which is not hepatic, is the amount of hemoglobin available for making bilirubin, and the amount of hemoglobin in turn depends on several factors, as destruction of blood, loss of blood, and diet.

Bollman and I⁹ have made attempts to determine whether we could correlate the amount of bilirubinemia with the amount of hepatic tissue present, or with the extent of hepatic injury. We found that the amount of bilirubin in the blood, as previously has been suggested, depends on many other factors than hepatic injury. For instance, an animal with obstruction to the biliary outflow will have a large amount of bilirubin in the blood a few days after the beginning of the obstruction, and at a time when the liver appears almost normal, and will have only a small amount of bilirubin in the blood several months after the obstruction, when the liver is very severely injured. An almost undetectable amount of bilirubin may be present in the blood of a dog the hepatic tissue of which consists of a single cirrhotic lobe, while intense jaundice will occur in a normal animal after administration of toluylendiamine, at a time when very little hepatic injury is demonstrable.

The bile salts appear to be products of activity of hepatic cells and to have at least one known function, that of assisting in the digestion of fat. Although no completely satisfactory methods are available for the determination of bile salts in body fluids, such methods as exist are sufficient to afford considerable information about the metabolism of these substances. Accurate methods for determination of bile salts in the bile have permitted Whipple³⁰ and his collaborators to draw the following conclusions from

their studies of animals with complete biliary fistulas. Daily excretion of bile salts is constant under constant dietary and physical conditions, dietary factors may affect the amount of bile salts formed, bile salts administered by vein or by mouth are rapidly and quantitatively excreted in the bile, the liver is probably responsible for the elaboration of bile salts, and slight hepatic injuries may greatly reduce the amount of bile salt formed and excreted. Bollman has modified the method of Gregory and Pascoe¹⁶ so that he has obtained fairly satisfactory results with the determination of bile salts in the urine and blood of dogs. He has made the following observation on the formation and determination of bile salts in normal animals, and on animals with different types and degrees of hepatic injury.³

The normal animal excretes only traces of bile salts in the urine, and bile salts are not definitely detectable in normal blood. Following intravenous administration of glycocholates or taurocholates only a small portion appears in the urine and the injected material rapidly disappears from the blood. Large amounts may be given by mouth without appearing in the blood, urine or feces. After complete removal of the liver, bile salts do not appear to be formed, but administered bile salts are quantitatively excreted in the urine within a few hours after injection. If biliary excretion is prevented by ligation of the biliary ducts, bile salts are excreted in the urine, but not all of the injected bile salts are recovered in the urine. It would appear that the liver plays a predominant part in destruction of bile salts as well as in their formation.

In the experiments with animals in which bile fistulas have been made, and with animals with complete obstructive jaundice, both formation and destruction of bile salts appear to be influenced by the condition of the liver. Excretion of bile salts in the urine in the presence of obstructive jaundice is definitely less than that in the bile in the presence of biliary fistulas. This appears to be due to the destruction of bile salts in the presence of obstructive jaundice, since administered bile salts are not all excreted, as they are in the presence of biliary fistula. Various agents which affect the liver reduce excretion of bile salts. Infection of the intrahepatic ducts, toluylendiamine, chloroform, carbon tetrachloride, or phosphorus poisoning may reduce excretion of bile salts to less than one-tenth of its former value. The greatest reduction occurs at the time of greatest hepatic injury, but marked reduction in excretion of bile salts may be obtained with hepatic injury too slight to be detected by ordinary histologic examination. The ability of the liver to destroy bile salts may not be altered, so that it would appear that the ability of the liver to form bile salts is easily impaired. Hepatic injury by toluylendiamine, carbon tetrachloride, or chloroform sufficient to give rise to urinary excretion of bile pigment, usually is accompanied by excretion of increased amounts of bile salts in the urine. If animals retain bile pigment in the blood from injury to the liver, or from uncomplicated biliary obstruction, increased amounts of bile salts may be found in their blood. Severe

hepatic injury reduces the amount of bile salts found in the blood, apparently by reducing the formation of these substances

A fairly accurate index of the condition of the livers of dogs with complete biliary obstruction was obtained by following the concentration of bile salts in the urine. The greater the excretion of bile salts under these conditions, the better has been the condition of the liver. Jaundice develops after a slight or moderate amount of hepatic injury, obstruction is associated with moderate excretion of bile salts. Improvement of the condition of the liver decreases the excretion of bile salts, but additional injury to the liver also diminishes excretion of bile salts. While the results of these observations would indicate that the concentrations of bile salts in the blood and urine are significant in postulating hepatic injury, it is questionable if such data can be used to quantitate hepatic function. The fact that the liver appears both to make and to destroy these substances would seem to preclude such a possibility.

THE USE OF DYES

The fact that the liver excretes many other substances, such as minerals and dyes, in the bile, has led to the common use of the rate of excretion of certain dyes as a method of estimating hepatic function. Since it is not the normal function of the liver to excrete these foreign substances, and since some of these tests are of clinical value, we believe they should not be called tests of hepatic function.

Most of our studies of dye methods for estimating hepatic function have been made by observing the rate of disappearance from the blood of an injected dye, such as bromsulphthalein or rose bengal. Many dyes may be used which appear to be specifically excreted by the liver. With a dose of dye that is entirely eliminated from the blood of normal animals in a few minutes, large amounts of the dye are found to be present in the blood several hours after injection into animals with complete biliary obstruction, or into animals from which the liver has been completely removed. Partial removal of the normal liver from animals, however, does not alter the excretion of dye in direct proportion to the amount of liver removed. If the remaining portion of liver is not injured by anesthesia or surgical trauma, little influence is noted after removal of more than half of the hepatic tissue, and a small amount of hepatic tissue (10 per cent) may take only twice as long to clear the blood of dye as is required by the liver of the normal animal. It should be emphasized that the remaining portion of liver of these animals is essentially normal, and that in all probability the normal hepatic cells do not become blocked by the dye but continue to pass it into the bile. In this way the fewer cells appear to be almost as efficient as a larger number working with a relatively smaller concentration of dye.

We have also attempted to correlate the results of dye tests with the amount of gross and microscopic pathologic change in the livers of animals

in various stages of cirrhosis caused by carbon tetrachloride. Specimens were immediately obtained at biopsy following completion of the dye test. It was immediately obvious that it was impossible to interpret the microscopic pathologic change in the liver from its gross appearance at exploratory laparotomy, particularly in the group of cases in which the liver appeared normal to gross examination, but had extensive microscopic changes. In general, the extent of pathologic change in the hepatic cells appeared to parallel the retention of the dye. The scirrhous changes in the liver apparently bore no relation to the excretion of dye. There were many exceptions, in which the results of dye tests failed to correspond to the pathologic change found in the liver. Some normal animals gave definite evidence of retention, and some animals with extensive gross and microscopic hepatic injury failed to retain any dye.

It would appear justifiable to conclude from these observations, in so far as the experimental animal is concerned, that the rate at which the liver removes a dye from the blood stream indicates how fast the liver will remove that particular dye from the blood stream at that time. When taken by itself it is not reliable in quantitating the extent of pathologic changes in the liver or how well the many other functions of the organ are being performed at the time the test was made. On the other hand, it may indicate hepatic injury and is probably as good a method as any developed to date for doing this.

ESTIMATES BASED ON CARBOHYDRATE METABOLISM

One of the most important functions of the liver has to do with carbohydrate metabolism. The liver is apparently either directly or indirectly responsible for maintaining the concentration of glucose in the blood. In this capacity it stores carbohydrate in the form of glycogen, which can readily be converted into glucose, and it can also make carbohydrate from proteins, and glucose from some of the other sugars. So many attempts have been made to measure hepatic function, and so many methods have been developed for it, based on this phase of hepatic activity, that it is impossible to review them adequately here.

Most of the tests concerning carbohydrate metabolism have been based on utilization of one of these sugars: dextrose, levulose, or galactose. All three are used in tolerance tests, and in addition, changes in the dextrose content of the blood following administration of drugs which produce hyperglycemia have been taken as criteria of hepatic function. Although it is true that hepatic activity is an important factor in removing an excess of dextrose from the animal organism and that there is a marked difference between the dextrose tolerance of a normal animal and that of a dehepatized animal,³² the fate of dextrose in the animal organism depends on so many extrahepatic factors that only under very special conditions could a change in glucose tolerance indicate impaired hepatic function. The use of a hyperglycemic agent to indicate hepatic injury is based on the facts that the liver

is the essential organ for producing hyperglycemia,^{19, 27} and usually an injured liver does not contain as much glycogen as the normal organ, therefore the hyperglycemia should be less in the presence of an injured liver. It should be noted that the glycogen content of the normal liver may vary within wide limits, from a minimum of less than 1 per cent to a maximum, as Butsch¹³ has shown, of more than 20 per cent. It can thus be seen that only under special conditions could this test be of significance. Bollman and I,⁹ using epinephrine as the agent for producing hyperglycemia, have attempted to use this test on our animals with reduced hepatic parenchyma, but have found it unreliable. However, it might be employed to advantage for specific purposes.

Although the liver does make glycogen from levulose, the muscles can do this also, and levulose can be utilized by an animal without a liver.⁶ Consequently, it is difficult to understand how a levulose tolerance test could be used to measure hepatic injury.

Theoretically it should be possible to indicate hepatic injury by a galactose tolerance test, as the utilization of this sugar appears to depend mainly on the liver.³³ However, as Millet³¹ has shown, the difficulty in employing this test experimentally is due to the wide difference in rate of utilization of galactose by the normal animal.

When all the known factors that enter into the metabolism of carbohydrate are considered—the rapidity with which it may be utilized by the normal animal and the slowness of its utilization by the fasted animal, its storage in large amounts in two major sites, liver and muscle, and the difference in the manner of utilization of the glycogen in these two sites, the enormous influence of insulin on it, the formation of fat from it, and when it is further recognized that there are probably many more factors to be discovered, as the recent work on the pituitary body and suprarenal gland would indicate, it would seem that the utilization of any phase of carbohydrate metabolism to measure hepatic activity, even though the liver has a major part in such metabolism, is almost hopeless. All the investigations on this problem made in our laboratory would tend to confirm this pessimistic outlook.

DETERMINATIONS BASED ON PROTEIN METABOLISM

The liver is essential for normal protein metabolism. Deamination,¹² formation of urea,^{5, 10} and oxidation of uric acid to allantoin^{8, 11} depend on the liver. None of these processes, when measured in the usual manner, occur in the dehepatized animal. On the other hand, an animal with greatly reduced hepatic parenchyma may carry on these processes at almost the same rate as the normal animal, with the exception of the formation of allantoin from uric acid.²⁰ The latter process is decreased by hepatic injury.¹

Green¹⁵ has studied the nitrogen partition in the blood and urine of dogs, when they were normal and after the development of various degrees of cirrhosis produced by carbon tetrachloride. He administered small quan-

tities of carbon tetrachloride to dogs, two or three times a week, for periods of from two to seven months. The animals were maintained under standard conditions and the total urinary excretion was analyzed daily for the main nitrogenous constituents. At various periods of time the nitrogenous constituents of the blood were also determined. From time to time the animals were etherized and the liver explored, its condition noted, and a specimen secured for histologic examination.

Definite lesions were produced in all of the animals. The lesions were progressive in nature, as was determined by exploration and histologic examination of the specimen secured. In the animals to which the drug was administered for several months, the liver became markedly cirrhotic.

During the production of the hepatic lesions, there were changes in both actual and relative amounts of nitrogenous constituents excreted in the urine. There was a decrease in the amount of urea, and an increase in the amount of ammonia, amino acids, and uric acid. Creatinine accounted for a fairly constant percentage of the total amount of nitrogen excreted. The most marked early changes were seen in the amount of amino acid excreted, which would almost double within a few days after beginning administration of the drug. Later, the amount of uric acid was the most altered, the increase amounting to several hundred per cent.

Our observations on the effect of hepatic injury on those phases of nitrogen metabolism in which the liver has been definitely proved to be involved, indicated that the hepatic injury cannot be quantitated by changes in excretion of the essential nitrogenous constituents. There remains, however, the possibility that a method of measuring hepatic function may be developed from utilizing one of its activities in relation to metabolism of nitrogen.

ESTIMATES DEPENDING ON SO-CALLED HEPATIC DETOXICATION

The liver usually has been considered as the site of destruction of many toxic substances. There is no question but that hepatic tissues will render inert many substances which are harmful to the organism. However, in only a limited number of instances has it been proved that the liver actually destroys the active agents. It is known that the liver is the site of destruction of almost all strychnine³⁴ that gains access to the body, and that it will destroy more nicotine² than all the other tissues of the body. On the other hand, it is not more active in causing epinephrine²⁸ and ephedrine³⁵ to disappear than the other tissues of the body. At present there is no method of determining whether the liver will destroy any given substance without direct experimentation. Adequate physiologic methods are at hand to determine whether the liver specifically destroys a substance, provided the substances under investigation can be estimated either biologically or chemically in the blood or tissues.

Many tests of hepatic function have been devised, based on the ability of the liver to destroy certain substances. In order to justify employment

of any substance for this purpose, it should first be demonstrated that the liver actually destroys all or a major portion of the substance, and it is necessary to have a method of quantitating the substance either directly or indirectly. Too often the sponsor of a given test has not troubled himself to fulfill both of these necessary requirements. There are very few tests, based on this phase of hepatic activity, in which it has been consistently proved that the test substance is actually destroyed in the liver.

Some very serious objections are encountered in attempting to measure the ability of the liver to destroy a given substance. Many of the substances so used are toxic to the liver or to the organism as a whole. This undesirable effect will be greatest in those instances in which the test is most desired, namely, where the hepatic parenchyma is reduced. The effect of the substance on the liver or organism often depends on the physiologic state of the liver at the time the substance was administered. The differences in effect of certain hepatic poisons on the glycogen-filled and glycogen-depleted liver is a good illustration. Furthermore, there may be a marked difference in the response to a given substance, depending on whether it is given when the subject is in a fasting or in a digesting state.

Owing to the considerations named we have not felt justified in using many of these tests in our investigations. Early in our work we discovered that although many of the substances used in an attempt to measure the capacity of the liver to destroy them would, in a given amount, be harmless to the normal dog, they might, in the same dose, cause severe reaction or death of animals with greatly reduced hepatic parenchyma. It should be noted, however, that there is a definite and possibly valuable field for investigators to discover a nontoxic substance, destroyed by the liver, which can be measured by some suitable method. At present such a substance does not appear to be available.

Numerous other supposed methods for measuring hepatic function have been described. Some of these tests are based on physiologic processes which have never been proved to be due to hepatic activity. Few of the tests, other than those previously given, appeared to have sufficient merit to justify investigations on experimental animals in our laboratory.

It should be noted that in our investigations we have taken the gross and histologic appearance of the liver as the standard for indicating the amount of hepatic injury. While we do not believe that such a standard is adequate, until a better one is developed it must suffice. For this reason I have confined this paper to a relation of our observations on attempts to correlate changes in known functions or activities of the liver in relation to the amount of hepatic tissue present or to the pathologic condition of the organ at the time the observations on function were made.

SUMMARY

A series of studies has been made to determine if a quantitative relationship could be found between the amount of apparently functioning

hepatic tissue and the capacity of such tissue to maintain any one of the many known functions of the liver. Methods were employed which would produce definite and permanent decrease in hepatic parenchyma. The amount of hepatic tissue possessed by the animals studied varied from normal to none and included a series of animals in which the hepatic injury was graduated from that in which the liver was severely injured acutely to that in which only a small amount of markedly cirrhotic hepatic tissue remained. Observations usually were made of the gross and microscopic appearance of the liver immediately after completion of each study of function.

Several important physiologic processes cease immediately after the liver is totally removed. Other processes are greatly modified. On the other hand, extreme reduction in hepatic parenchyma, as much reduction as it was possible to produce and have the animal survive, produced slight or no changes in those physiologic processes which were abolished or modified by total removal of the organ. The results of our studies would indicate that extreme caution must be used in attempting to postulate the pathologic condition of the liver of an individual by the results of the so-called hepatic function tests. In these studies none of the many methods for measuring hepatic functional capacity which we tried were wholly reliable in indicating to us the approximate extent of reduction of hepatic parenchyma, and injury to hepatic parenchyma, as determined by gross and microscopic observations made immediately after completion of the test. While several of the tests may be of value clinically, it would seem that unless their use is combined with other methods of determining hepatic disease they may cause serious error.

BRONCHOSCOPY IN PULMONARY DISEASE

PRESENT STATUS AS AN AID IN DIAGNOSIS AND TREATMENT

By GABRIEL TUCKER, M D , *Philadelphia, Pennsylvania*

THE use of the bronchoscope as an aid in the diagnosis and treatment of diseases of the lung has been practically a development of the last decade. Before that time the bronchoscope was used chiefly for the removal of foreign bodies. The modern bronchoscopic technic, using the distally lighted tube of Jackson, without general anesthesia, has widened the field of its usefulness to such an extent that bronchoscopy is indicated in practically every disease of the lung, at some time during its course, in some particular patient. In modern bronchoscopy general anesthesia is not required. In acute inflammatory conditions of the lung, as well as in dyspnea produced by obstructive lesions, general anesthesia is contraindicated, and in these conditions bronchoscopy may be of the greatest aid both in diagnosis and treatment. When we speak of modern bronchoscopy we refer to the technic as originated by Dr. Chevalier Jackson, and as developed by him and his coworkers in the various bronchoscopic clinics in Philadelphia.

Personal course postgraduate teaching has created a world-wide interest in bronchoscopy. By intensive courses for special instruction in bronchoscopic technic and the clinical application of the procedure, established in one school, the Graduate School of Medicine of the University of Pennsylvania, 636 physicians from the United States have received preliminary training in cadaver and dog work and clinical instruction in bronchoscopy. These physicians have come from practically every large city in every state in the United States. There have come also 87 student physicians from 19 foreign countries and states, including Canada, the South American States, the British Isles, three Central European states, China, Japan, Australia, South Africa and New Zealand. These student physicians were for the most part well established otolaryngologists prior to their taking the work in bronchoscopy. With adequate equipment and a trained personnel they have carried on the work on their return home and many reports have come to us of the success of their work in bronchoscopy.

The aid rendered by bronchoscopy is so essential both in diagnosis and treatment that the time will come when a bronchoscopic clinic will be as much a part of a hospital that treats pulmonary diseases as is the roentgenologic department. Bronchoscopy will, however, always supplement roentgenology in the matter of diagnosis, because the function of the bronchoscope

* Read at the Chicago meeting of the American College of Physicians, April 16, 1934.
From the bronchoscopic clinics of the University of Pennsylvania, the Hospital of the University of Pennsylvania and the Graduate Hospital of the University of Pennsylvania.

is to look into the lung and the function of the roentgen-ray is to look through it

Bronchoscopy as an Aid in Diagnosis The first bronchoscopic examination is essentially a diagnostic study and in every case will give findings supplementary to other methods of examination. The larynx, trachea and larger bronchi can be inspected without general anesthesia by the use of distally lighted instruments. They are made of such size that even the new-born infant can be examined¹ without trauma, if the proper technic is followed.

Among the points noted in the bronchoscopic examination may be mentioned the appearance of the bronchial mucosa, the quantity and character of secretion, evidence of abnormality of the lumen of the trachea and bronchi, evidence of abnormal mobility, fixation or deviation of the trachea and bronchi and, finally, a careful inspection of the bronchial movements during respiration and cough. The location and extent of the lesion as seen intrabronchially is of first importance. The origin of pus or abnormal secretions from a branch bronchus gives an indication of the lesion in the area of lung supplied by the branch bronchus in question. The relative quantity of air that is passing in and out may be roughly estimated. The presence of bronchial dilatation, compression stenosis, intrabronchial lesion, growths, ulceration or infiltration can be readily determined. The significance of bronchoscopic findings should be interpreted with a knowledge of the findings obtained by the internist on physical examination and the results of roentgenologic studies. The removal of secretions uncontaminated by mouth organisms, and of specimens of tissue for biopsy, where the appearance of the local lesion in the opinion of the bronchoscopist justifies it, will give positive information that cannot be obtained by any procedure other than bronchoscopy.

Bronchoscopy for Treatment The purpose of bronchoscopic treatment is to establish and maintain a functionally normal airway throughout the tracheobronchial tree so that there may be a state of normal ventilation and drainage in the lung. Bronchoscopic aid is principally through the removal of obstruction. Obstruction may be due,

- 1 To foreign body, aspirated or endogenous,
- 2 To stenosis or deformity of the bronchi,
- 3 To tissue obstruction from inflammatory or neoplastic change,
- 4 To secretion, normal or abnormal

Foreign Body Bronchoscopic removal of foreign body, with 98 per cent cure is generally accepted as the only worthwhile method of treatment. This applies either to aspirated or to endogenous foreign bodies. Bronchoscopic removal is accomplished by the use of forceps through the bronchoscope and by those trained in bronchoscopic procedure is accomplished without general anesthesia. In cases where the foreign body has passed beyond the point where it can be seen through the bronchoscope,

biplane fluoroscopic guidance may be used. If the bronchoscopist and roentgenologist have mastered a cooperative technique, the procedure is usually without serious risk. In cases of foreign body where the density of the object is such that it can be localized only on the roentgen-ray film and not fluoroscopically, the technique of Pancoast and Pendergrass can be used and opaque markers placed in such a position that roentgenoscopic localization may be made and bronchoscopic removal successfully carried out under fluoroscopic guidance.² (See Case 2.)

Bronchial Stenosis It is evident that the character of the lesion producing the stenosis will determine the desirability of bronchoscopic dilatation. A simple cicatricial stenosis of the bronchus may be dilated readily by direct vision by use of the bronchoscope. A compression stenosis may also be dilated bronchoscopically. The nature of the compression should, however, be known and its character should determine the method of treatment.

Stenosis due to inflammatory tissue is frequently amenable to bronchoscopic treatment. Benign endobronchial neoplasms may be removed bronchoscopically. Malignant tissue may be removed, and radon may be implanted in obstructing tissue, with removal of obstruction and relief of the secondary infective processes that so frequently are due to obstruction of the bronchus by malignant neoplastic tissue. In cases of cancer of the lung with bronchial stenosis, the results of irradiation treatment can best be determined by bronchoscopic examination.

Bronchoscopic Removal of Secretions The bronchoscopic aspiration and removal of secretions that obstruct the airway is probably the most important contribution of the bronchoscope, aside from foreign body removal. In certain conditions where the cough mechanism has been temporarily impaired, postoperatively or post-partum, acute edema of the lungs and acute obstruction by retained secretion result, as in massive collapse of the lungs. The patient is unable to free the tracheobronchial tree from obstruction. The same conditions sometimes occur in asthma.³ In this type of case the mechanical removal of obstructing secretion through the bronchoscope prevents asphyxial death and produces a cure that seems little short of miraculous. In inflammatory lesions, particularly in post-operative pulmonary complications, bronchoscopic removal of obstruction prevents the more serious lesions such as lung abscess, etc. In subacute and chronic pulmonary infections bronchoscopy may prevent bronchiectasis. This is particularly true of unresolved pneumonia, purulent tracheobronchitis, purulent tracheobronchitis with drowned lung and drowned lung where the secretions are retained after the removal of foreign body. The bronchoscopic removal of secretions from the bronchi aids ventilation and drainage and allows the inflammatory processes to resolve. Repeated bronchoscopic aspiration has, in many patients, completely restored the lung to normal.

Bronchoscopic aspiration removes the secretion in two ways. First by direct aspiration through the bronchoscope or aspirating tube. With

a flexible-tipped aspirating tube, bronchi that diverge at an angle from the main bronchi may be aspirated. The curved flexible tip permits aspiration around the corner. Second, bronchoscopic treatment brings about removal of secretion by the production of "selective cough."

"Selective Cough" as a Means of Pulmonary Drainage On the introduction of the bronchoscope or aspirating tube into the uncocainized area of lung, there occurs a deep inspiratory effort with an extreme widening of the bronchial orifices and a violent expiratory effort which frequently can be seen to force casts of the smaller bronchi and plug-like masses of purulent secretion into the lumen of the larger bronchi in front of the bronchoscope. The removal of the obstructing material from the smaller bronchi allows free drainage of the area of lung beyond, and as a result, we find that the patient frequently continues for several days to bring up large quantities of secretion. During this time there will be evidence on physical examination that the lung is clearing. This is one of the most important results of bronchoscopic aspiration.

Bronchoscopic Medication and Disinfection in Pulmonary Disease The introduction of medication bronchoscopically does not have a satisfactory status at the present time. It certainly is undesirable to instil oils into the lung as medication, or to flood the lung with anything in the nature of an antiseptic solution. The introduction into the larger bronchi of a mild antiseptic solution such as 1 to 10,000 mercuraphen, followed by bronchoscopic aspiration, may be desirable, not so much because of the disinfecting power of the solution as that it acts as a diluent and permits the removal of tenacious secretion, thereby allowing free drainage. At the suggestion of the author and Dr. Chevalier Jackson, Dr. John A. Kolmer carried out a very interesting series of experiments in animals in bronchial disinfection and immunization.⁴ However, the practical results of this experimentation have not as yet been fully determined. It would seem when substances, either chemical, bacteriological or serological, are produced, suitable for use in the lung for sterilization and disinfection that the best method of application will be through the bronchoscope because the medication can be controlled and restricted to the diseased lobe of the lung. When a considerable quantity of fluid material is introduced into the lung, it should be reaspirated promptly. If it is not aspirated, one should, from the local condition of the lung, be reasonably certain that it would be removed promptly by cough. In the use of iodized oil for pneumonography particular care is used not to force the opaque material into the lung but to allow gravity and the respiratory efforts to carry it in.

As an adjunct to free drainage, all medication that will tend to prohibit the normal cough mechanism should be withheld, particularly opiates and other cough sedatives. The use of atropine is also undesirable because it increases the viscosity of pulmonary secretions and makes it more difficult to expel them from the lung by the cough mechanism.

Dr William F Moore, at the Philadelphia General Hospital, has obtained very favorable results from the bronchoscopic intrabronchial application of polyvalent bacteriophage prepared from stock culture⁵ This type of bacteriophage seems at the present to give us the most hope for benefit in the field of intrabronchial medication The best method of application is by means of the bronchoscope, because the field of application can be limited, its action noted by inspection, and the procedure better controlled

Contraindications to Bronchoscopy There are few contraindications to bronchoscopy where there is a positive indication for its use In every case in which it is possible a careful roentgen-ray examination and a physical examination by a competent internist should be made, prior to bronchoscopic examination

Modification of Bronchoscopic Technic In patients urgently dyspneic where there is evidence of bronchial obstruction, as in postoperative pulmonary complications, bilateral atelectasis, acute edema of the lungs such as is seen occasionally post-partum in heart lesions, bronchoscopy may be done for the removal of obstructive secretions without removing the patient from the bed⁶ In a number of instances in a grave emergency of this type, bronchial obstruction has been relieved by bronchoscopic aspiration of secretions The limit of the use of bronchoscopy where it is indicated, then, must be a matter of the efficiency of the bronchoscopic technic

Illustrative cases of the results of bronchoscopic aid in the diagnosis and treatment of conditions which occur frequently in the ordinary run of patients seen by the internist are here presented

Chronic Cough Chronic unexplained cough in a patient who has been studied carefully by the usual diagnostic method is frequently encountered A simple bronchoscopic inspection of the tracheobronchial tree will reveal the cause in many cases and afford a means of treatment that will cure the condition

CASE I

Chronic cough, bronchial obstruction, localized bronchial dilatation

A male, 45 years of age, an attorney referred by Dr William MacMurtrie of Philadelphia, had chronic intermittent coughing attacks, more severe at night, over a period of years The patient was well nourished and not otherwise ill The strangling cough became so severe that he was unable to follow his occupation The condition had been variously diagnosed as chronic bronchitis, asthma, etc Finally the patient's condition became progressively worse and a careful roentgen-ray check-up and physical examination revealed an abnormal density and area of dullness in the posterior portion of the right lower lobe Bronchoscopic examination revealed a tumor mass blocking the posterior division of the right lower lobe bronchus The obstructing tissue was removed bronchoscopically and found to be inflammatory tissue, and a localized area of bronchiectasis secondary to the obstruction of the bronchus was demonstrated by lipiodol (Figure 1) After removal of the tumor bronchial drainage was restored, the dilated bronchi returned to normal and the patient's symptoms entirely disappeared The patient has been well three years

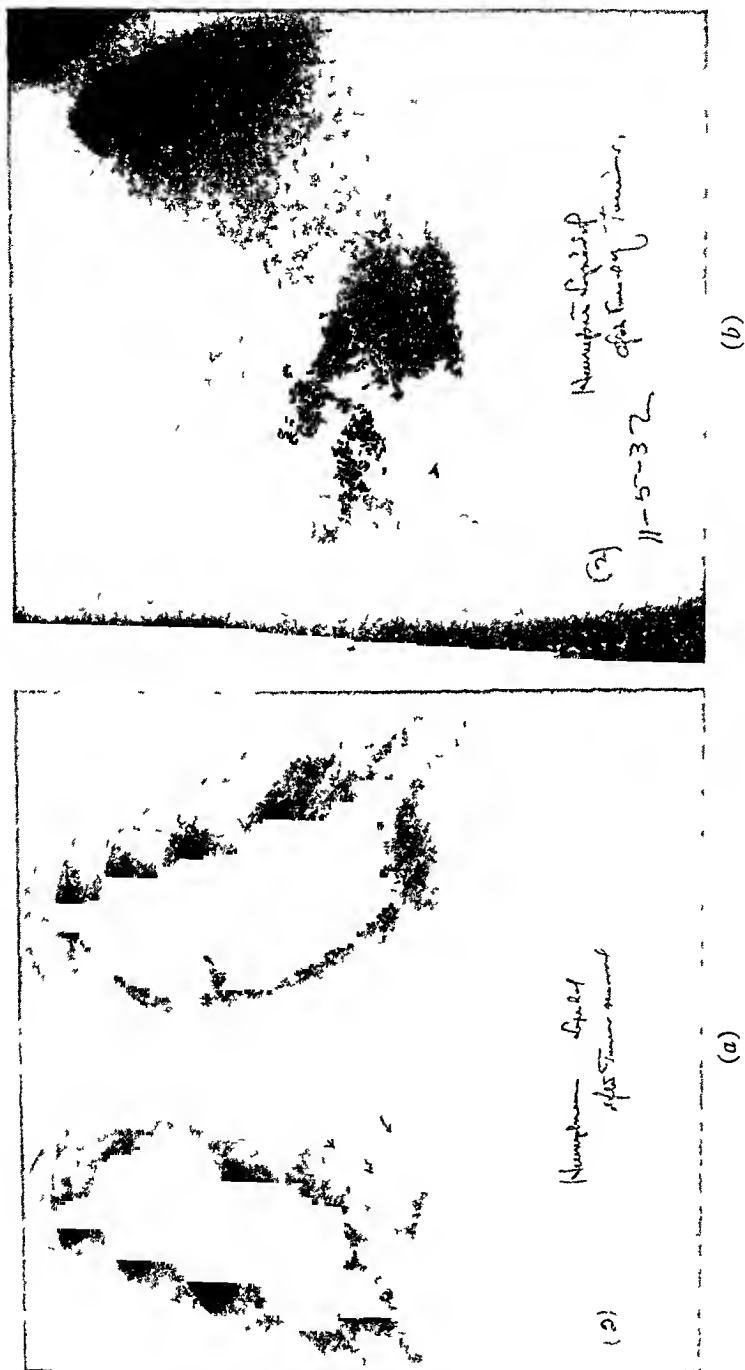

FIG 1 Case 1

Bronchoscopic lipiodol pneumonogram showing the area of bronchial dilatation distal to the location of tumor
 (a) Anteroposterior
 (b) Lateral

The lipiodol was coughed out. The lung cleared completely after six bronchoscope treatments.

Hemoptysis Active pulmonary hemorrhage is practically always a contraindication to bronchoscopic examination. Where the condition is not definitely due to tuberculous infection, bronchoscopic examination in the interval between periods of hemoptysis will frequently establish a diagnosis. Overlooked foreign body, carcinoma of the lung, benign tumor of the lung, inflammatory granulation in a bronchiectatic cavity, ulcerative lesion of the bronchus, broncholithiasis, granuloma of the bronchus, pulmonary tuberculosis in which acid-fast organisms had not been demonstrated from sputum examination, each has been established definitely, by bronchoscopic examination, as the cause of hemoptysis.

CASE II

Hemoptysis, overlooked foreign body

A male, 29 years of age, had had a slight hemorrhage five weeks before admission, a week later a severe hemorrhage, a week following this a third hemorrhage, and three days later a fourth. After several roentgen-ray examinations were made a small dense shadow was detected in the lower lobe of the right lung, near the right border of the heart. In going back over the history it was found that the patient had had extraction of teeth under general anesthesia 15 years and nine years before admission. Following the second tooth extraction there had been a dry cough. The patient's general condition had been otherwise good. The diagnosis of foreign body in the lung was made by Dr. Channing Frothingham of Boston who referred the patient. A special roentgen-ray examination showed that the dense shadow was probably a fragment of a tooth. Bronchoscopy for removal of the foreign body was done under fluoroscopic guidance at the University of Pennsylvania Hospital, after roentgen-ray localization of the tooth by Dr. Pancoast and Dr. Pendergrass, and the foreign body removed (Figure 2 *a, b, c*). In order to obtain fluoroscopic guidance it was necessary to use a special method of localization. Opaque markers were placed anteroposteriorly and laterally with the patient in the recumbent position after the method of Dr. Pancoast and Dr. Pendergrass, because the tooth was not dense enough to be seen fluoroscopically although it could be demonstrated very well on a *Bucky* film. This case illustrates overlooked foreign body as a cause of pulmonary hemorrhage, and also demonstrates the effectiveness of properly guided fluoroscopic bronchoscopic removal of a foreign body that was not sufficiently opaque to be seen on fluoroscopy.

Bronchial Tumors, Benign and Malignant The diagnosis of bronchial tumor is made certain in a great majority of cases by bronchoscopic examination. Biopsy is possible in many tumors both benign and malignant. Benign tumors may be removed endoscopically while malignant tumors may be treated by radon implantation through the bronchoscope. The secondary pathology, drowned lung, abscess, etc. may be benefited during the irradiation treatment by repeated bronchoscopic aspiration of secretions from the obstructed area of lung. This is especially emphasized by Dr. Eugene Pendergrass who insists on bronchoscopic drainage during the irradiation treatment of his cases of pulmonary tumor. Tumors of the mediastinum and the lung itself may also be diagnosed by bronchoscopy in a percentage of cases.⁶ Occasionally a pulmonary tumor may give esopha-

FIG 2

- (a) Roentgenogram showing tooth shadow at the junction of the diaphragm and heart shadow. Tooth shadow could not be seen fluoroscopically.
- (b) Roentgenogram showing opaque marker in position. Pencoast-Pendergrass technic. Markers could be seen fluoroscopically and were so placed that they served as guides for the location of the tooth during bronchoscopic removal. The bronchoscopist used the sense of touch as a guide in grasping and withdrawing the tooth.
- (c) Fragment of tooth after removal.

geal symptoms, due to periesophageal extension, and the differential diagnosis can be made only by bronchoscopic examination (Figure 3)

CASE III

Primary carcinoma of the lung, metastatic extension producing compression stenosis of the esophagus

Male, aged 58 years The patient was referred because of dysphagia and loss of weight by Dr J S McKee of Norfolk, Virginia He was emaciated and able to swallow only liquids He complained of cough only when lying down Roentgen-

FIG 3

(a) Roentgenogram showing evidence of peribronchial thickening at the left base On bronchoscopy, tissue removed from left lower lobe bronchus showed carcinoma

(b) Lateral film, with opaque mixture, shows stenosis of the lower esophagus Esophagoscopy showed compression, no ulceration The triangular area in front of the shadow of the lower esophagus represents atelectasis due to bronchial occlusion by the cancer in the left lower lobe

ray examination showed a stenosis of the esophagus involving the lower third, evidence of an old tuberculous lesion in the apices of both lungs, and increase in density at the left base, the suggestion being that this might be due to a bronchiectasis The esophagoscopy examination revealed an annular stenosis involving the lower third of the esophagus, and on passing a small esophagoscope in the strictured area the mucous membrane was found to be smooth, the lesion apparently being periesophageal with no ulceration

Because of the roentgen-ray evidence of a lesion in the left lower lobe, bronchoscopic examination was made which showed an organic stenosis of the left lower lobe bronchus with firm infiltration and ulceration of the bronchial wall Histologic diagnosis by Dr E A Case was "bronchial carcinoma," from bronchoscopic biopsy The bronchoscopic finding in this case enabled us to make a diagnosis of primary

carcinoma of the bronchus with periesophageal extension producing compression stenosis of the esophagus. These findings were confirmed later in this patient by autopsy.

Tuberculosis In the ordinary case of uncomplicated pulmonary tuberculosis with a positive sputum there is no indication for bronchoscopy. In suspected cases where the sputum is negative, bronchoscopically removed secretion from the involved area of lung frequently shows tubercle bacilli and confirms the diagnosis. The presence of a tuberculous infection is not a contraindication to bronchoscopic examination. A persistent wheeze, obstructive emphysema, obstructive atelectasis or drowned lung are indications for bronchoscopy.

CASE IV

Pulmonary tuberculosis, bronchial stenosis

Female, aged 40, referred by Dr Frank Burge of Philadelphia because of a persistent expiratory wheeze and evidence of emphysema of the left lung. Dr Burge had made a diagnosis of tuberculosis in this patient, had placed her in a sanatorium and, with pneumothorax treatment, had arrested the disease. The patient had gained weight to above normal, and the sputum was free of tubercle bacilli. Physical ex-

FIG 4 Case 4

(a) Anteroposterior chest film, taken on inspiration, showing the heart in normal position.

(b) Anteroposterior film on expiration showing displacement of the heart to the right, marked depression of the left diaphragm, the characteristic findings of obstructive emphysema.

Bronchoscopic examination showed the obstruction to be due to tuberculous granulation tissue obstructing the left main bronchus.

amination gave evidence of bronchial stenosis and roentgen-ray examination showed marked obstructive emphysema of the left lung. Bronchoscopic examination revealed fungating masses of tissue in left main bronchus which obstructed the airway to such an extent that the left bronchus was almost completely blocked on expiration. The tissue masses were removed bronchoscopically and the tissue, examined by Dr E. A. Case, was reported as showing "chronic exudate and tissue the seat of tuberculosis".

Removal of the masses relieved the bronchial obstruction to a considerable extent and so far there is no evidence of recurrence of this type of tissue. There is, however, evidence of stenosis of the left main bronchus which has been relieved by bronchoscopic dilatation. A full report of this case will be made subsequently by Dr. Burge.

Suppurative Disease of the Lung In every patient with suppurative lesion of the lung, unless it is one in which there is pleural involvement with urgent demand for external surgery, bronchoscopic investigation as an aid to diagnosis and localization of the lesion should be carried out.

Bronchiectasis Bronchoscopic examination will reveal the condition of the interior of the larger bronchi. Aspiration of secretion and bronchoscopic pneumonography will best demonstrate the extent of the lesion. If bronchial obstruction can be relieved by intrabronchial treatment the function of the diseased area of lung may be restored. If no improvement results the information obtained by the study will be of aid to the surgeon in classifying the condition for surgical treatment, that is, it will help to decide whether the patient has a "first, second or third degree bronchiectasis".⁸ In advanced bronchiectasis, bronchoscopy is palliative only, and if surgery is not done, bronchoscopic treatment combined with postural drainage and medical care will make the patient's burden easier. Every case of bronchiectasis should have careful bronchoscopic study before the diseased area of lung is excised.

Prevention of Bronchiectasis by Bronchoscopy There is much controversy regarding the exact etiology of bronchiectasis. There is, however, a factor which has been emphasized little except by Chevalier Jackson, namely, localized infection of the lung, with obstruction to the normal bronchial drainage. There are a number of pathological conditions which are undoubtedly followed by bronchiectasis in which, if normal drainage is restored and maintained by way of the tracheobronchial tree, bronchiectasis will be prevented. Of these conditions may be mentioned unresolved pneumonia, purulent tracheobronchitis, localized infection with obstruction and drowned lung, pulmonary changes following the sojourn of foreign body.

CASE V

Unresolved pneumonia

Female, colored, aged 25, referred from the service of Dr. George M. Piersol, Graduate Hospital, University of Pennsylvania. This patient had developed an extensive lesion in the right chest which had been under observation for a period of six weeks. The course of the disease was at first typical of pneumonia, her temperature then became septic, and the lesion extended until it involved the entire right lung. Her general condition remained about the same (Figure 5). The lung

failed to clear and she was referred for bronchoscopic examination. Following the first bronchoscopy there was very profuse expectoration of foul pus. A second bronchoscopy was done three days later. Her temperature then remained normal, the quantity of pus expectorated gradually lessened. Four bronchoscopic treatments in all were given. Her condition improved to such an extent that she was dis-

FIG 5 Clinical chart showing the course before, during and following bronchoscopic treatment

charged from the hospital after two weeks treatment. She has been kept under observation as an out-patient for a period of six months and her lung is entirely clear (Figure 6)

Postoperative Pulmonary Complications Postoperative pulmonary complications, in many cases, require bronchoscopic examination as a means of differential diagnosis to exclude aspiration infection or foreign body. Bronchoscopy should be done early as a diagnostic examination and it will

very frequently promote drainage to such an extent that prompt resolution of the condition will occur

In massive collapse where other measures do not promptly restore the lungs to normal, bronchoscopic aspiration will open the airway and restore ventilation and drainage. One of the most important factors in the production of postoperative pulmonary atelectasis is impairment of the cough

FIG 6 Roentgenogram showing the chest condition before bronchoscopic examination and after bronchoscopic cure

mechanism as the result of operative procedure. In these cases bronchoscopy may be required to supplement the coughing efforts in the removal of obstructive secretions.⁷

CASE VI

Postpartum edema of the lungs

A woman, 35 years of age, was referred by Dr Arthur First of Philadelphia. She had been delivered of a normal child at term without instrumentation. The patient had a mitral stenosis, well compensated. Within 24 hours she developed an acute edema of the lungs although her heart condition was pronounced by Dr Henry Smookler to be satisfactory. When seen in consultation she was propped up on a back rest. The tracheobronchial tree was rapidly filling with secretion which she was unable to remove by coughing efforts. The medical consultant assured us that her heart condition warranted bronchoscopic aspiration. A modified bronchoscopic technic was used without removal of the patient from bed. About 150 cc of thin brownish secretion were aspirated from the tracheobronchial tree. Dyspnea was immediately relieved, there was no recurrence of the pulmonary edema, and the patient progressed to an uneventful recovery (Figure 7)

FIG 7 Clinical chart showing patient's condition at and subsequent to bronchoscopic removal of obstruction.

CONCLUSIONS

1 Due to the perfection of instrumentarium and of the method of bronchoscopic procedure without general anesthesia, bronchoscopy has reached a point in development where it is invaluable as an aid in the diagnosis and treatment of pulmonary disease

2 The bronchoscopic findings will supplement all other methods of examination in pulmonary disease. In order to obtain the best results, special training and continuous practice by the bronchoscopist is required, together with a trained personnel, adequate instrumentarium and the support and close cooperation of the internist, the roentgenologist and the surgeon.

3 Modern bronchoscopy has developed a world-wide interest because of its efficiency as an aid in the diagnosis and treatment of pulmonary disease. Its continued advance and development will depend upon the interest and support given by the internist and the pediatrician who see the patients first and who decide whether or not the patients shall have the benefit of bronchoscopic consultation.

THE IMPORTANCE OF ACTUALLY MEASURING THE TOTAL HEAT PRODUCTION

By L. H. NEWBURGH, *Ann Arbor, Michigan*

A KNOWLEDGE of the basal metabolism is informative in many different problems. Its diagnostic value is quite familiar, but its use as a basis for estimating the total production of heat is open to errors which are sometimes so large that the observer is seriously misled.

In the pursuit of our own studies, it became of paramount importance to be possessed of a means of knowing accurately how much energy was dissipated day after day so that we could compare the inflow of calories with their expenditure. This we were able to do by the development of Benedict's¹ study of the insensible perspiration. Time does not permit a discussion of the method. It is described in detail in our publications². Suffice it to say here that it is capable of yielding extremely accurate data when the proper precautions are followed.

The earlier way of estimating the total heat production consisted of adding to the basal metabolism, theoretical increments appropriate for the activity of the subject.

In 1918, as a war measure, Lusk³ made such prediction tables. The average weight of thousands of individuals of a given height at 35 years of age, was calculated. The normal basal metabolism was then figured by means of the DuBois height-weight formula. To these basal values, 10 per cent for 16 hours was added to provide for sitting and standing. Tables for the extra calories per hour attributable to various occupations were then consulted and the values for an eight hour day corresponding to the occupation were added to the sum already obtained. A final increment of 200 calories for men and 150 calories for women was included to account for small movements such as dressing. Part of the information may be seen in table 1. The theoretical basal metabolism was 1700 calories for 24 hours.

TABLE I

| Predicted Increment Corresponding to Activity Per cent of Basal | Total | Type of Activity |
|--|-------|------------------|
| 6 | 1800 | Bed |
| 40 | 2375 | Tailor |
| 60 | 2730 | Shoemaker |
| 94 | 3300 | Carpenter |
| 160 | 4400 | Stone Mason |
| 196 | 5025 | Woodsmen |

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934

It must be remembered that these predictions were theoretical and that no test of their accuracy was made. The first three values are strikingly low. It is especially difficult to accept the statement that the patient in bed expends only 100 calories beyond the basal. Most writers have assumed that 20 to 30 per cent needed to be added to the basal metabolism to arrive at the total expenditure of energy for persons in bed. It requires only a moment's thought, however, to make one realize that the variations from patient to patient must be large. It seems unlikely that any general prediction for this group of persons can have much value.

We have applied our method for measuring total heat production to three youths who had been in bed for some months because of minimal tuberculosis of the lungs. All were afebrile and entirely free of symptoms. It might be supposed that their long experience in bed had taught them to be reposeful. The facts revealed by actual measurement came as a great surprise to us.

TABLE II
Basal and Total Production of Heat by Boys Continuously in Bed

| Patient | Basal Metabolism Cal for 24 Hours | Total Metabolism | |
|------------|--------------------------------------|------------------|-----------------------------------|
| | | Cal for 24 Hours | Increment in per cent of basal |
| E P age 18 | 1550 | 2558 | 65 |
| C S age 15 | 1550 | 2325 | 50 |
| H J age 18 | 1580 | 2350 | 49 |

Nor were the total calories increased when these patients were permitted the freedom of the room.

We had a similar experience with a normal subject who was first in bed for a week and was then allowed to move freely about the room during the second week. These experiences give rise to the question whether anything is gained by forcing patients to remain continuously in bed when they do not feel ill enough to stay there voluntarily. Perhaps they would often expend less energy if they were permitted to make themselves comfortable within the confines of a large and pleasant room.

We have also recorded the heat production of a series of men and women while they were pursuing their usual modes of life. Table 3 contains the data. The increment of expenditure of energy varies from 53 to 120 per cent. Leaving out the last subject, it is noteworthy that a group of young people, none of whom was earning his livelihood by manual labor, expended an amount of energy roughly equal to their basal metabolism as a result of the day's activities. Examination of the individual values should convince the reader that a prediction of the total heat production for any one of the subjects would be liable to a large error.

We have determined the total dissipation of energy by obese persons and compared these values with the calories of the diet. We have then predicted

TABLE III
Total Energy Metabolism for Various Activities

| Sex | Age | Wt Kg | Ht Cm | Basal Me- tabolism Cal for 24 Hours | Total Metabolism | | Occupation |

the loss of weight and in that way we have convinced ourselves that all obese persons will lose weight when they are underfed, and what is more important, that these individuals have invariably become fat simply and solely because they have eaten too much

We have recently had the opportunity of studying a patient of the type described by Cushing. The outstanding characteristics are uniform decalcification of the skeleton and adiposity of the upper half of the body. Figure 1 shows the patient, 19 years old, who is only 5 feet tall, when he weighed 180 pounds. You will note that his legs and arms are not at all fat but that he appears to possess a huge deposit of adipose tissue in the chest and abdomen. This apparent localization of the fat lends an air of mystery to the situation and is generally interpreted as evidence that the gain in weight is not merely due to overeating. The baneful intervention of an endocrine gland is suspected. After this patient had lost 50 pounds in response to a diet of about 900 calories, photographs were made again (figure 2). This time the weight of 132 pounds is normal and still the chest and abdomen are as protuberant as they were in the beginning. Examinations by the roentgen-ray (figure 3) show that the spine is unusually short and hence much less than the normal space was provided for the organs. The necessary room has been obtained by an upward and outward movement of the ribs. What superficially appears to be a localized accumulation of adipose tissue is in fact merely the configuration of a deformed skeleton. As further evidence that there is nothing peculiar about the obesity of this patient, attention is called to figure 4. The solid line represents the actual loss of weight in response to underfeeding. The broken line indicates the predicted decline in weight calculated from the difference between the total expenditure of energy and the calories of the diet. It is difficult

FIG 1

FIG 2

FIG 3

to believe that an individual, whose weight during a period of 54 days was reduced by underfeeding to within 22 grams of the predicted value, could have become fat for any reason other than overeating

The next patient is interesting because of the dramatic response to undernutrition. He exhibited enormous localizations of adipose tissue and his initial weight of 560 pounds was astoundingly great. Both features are often credited with being signs of endogenous obesity. His appearance at the beginning of treatment is shown in figure 5. During the ensuing year his diet afforded him 300 calories a day. This effected a loss of weight of 287 pounds (figure 6). During the second year he received 600 calories daily and lost 93 more pounds. He now weighed 194 pounds, a weight that was considered satisfactory for his height. He was now told to keep his weight stationary by judicious selection of his food. How well he succeeded is shown in figure 7, taken nine months after he had been told that he had lost a sufficient amount of weight, since he weighed the same amount.

FIG 4

Grafe,⁴ in his book published within the year, states that obese individuals who maintain their weight for a period of time in spite of underfeeding, are victims of endogenous obesity. If this were true, the responses portrayed in figure 8 could not have occurred. This adipose female who was in bed throughout the study expended close to 2500 calories daily. When her diet contained that number of calories, she neither gained nor lost weight (first period). She next received about 1800 calories from a diet high in carbohydrate—260 grams daily. She responded by a steady loss of weight (solid line) that corresponded with the predicted loss (broken line). In the final period she also received about 1800 calories but now the diet contained little carbohydrate and much fat. This caused an initial precipitous loss followed by a period during which she did not lose weight. Since both types of response were produced in the same individual by manipulation of the diet, I think you will agree that the manner in which the weight responds to dietary treatment is not determined by something within the individual but rather by the character of the diet.

Furthermore, this ability to maintain the weight in the face of underfeeding is not the sole possession of obese persons since we have reproduced

FIG 5

FIG 6

FIG 7

FIG 8

it in the normal as may be seen in figure 9. This normal man who was in bed throughout the study, received 1078 calories daily in the form of 69 grams of protein, 91 grams of fat and 148 grams of carbohydrate. He

FIG 9

dissipated 1688 calories a day. The diagram shows a period of five days during which he destroyed 475 grams of bodily tissue. Nevertheless he gained 115 grams of weight in these five days. Clearly a phenomenon displayed by a normal man cannot be classed as a specific sign of disease.

CERTAIN ASPECTS OF PULMONARY ABSCESS FROM AN ANALYSIS OF 210 CASES¹

By DONALD S KING, M D , F A C P , and FREDERICK T LORD, M D ,
F A C P , *Boston, Massachusetts*

CERTAIN aspects of pulmonary abscess are presented as a continuation of the study of this disease at the Massachusetts General Hospital. Two hundred and twenty-seven cases occurring between 1909 and 1924 have been analyzed by one of us^{1,2}. The present series embraces 211 cases observed from 1924 to 1932. As of this number all but one has been followed to the termination in death or present condition from two to nine years after discharge, the discussion to follow is based on the 210 cases. For the unusual success in the follow-up we are indebted to Miss Eleanore A. Lewis and Mrs. Alice R. Coghlin.

Though the cases under discussion are all classed as lung abscess, the designation lung gangrene would be equally appropriate for the great majority of the series, inasmuch as in 192 cases the sputum is recorded as foul. No note as to the odor is recorded in 14 and the sputum was said not to be foul in four. There was no sputum in one case in which abscess was found at autopsy.

PREDISPOSING FACTORS

The etiologic importance of operations about the upper respiratory tract has increased. While one out of every three cases of abscess could be traced to such a procedure in the 227 cases occurring between 1909 and 1924, the proportion in the present series has risen to about one in two cases (117 of 210 cases, or 55.7 per cent). The operative procedures included the removal of tonsils and adenoids in 81 (38.6 per cent), the extraction of teeth in 26 (12.4 per cent) and an upper respiratory operation in 10 (4.8 per cent). The increase in the proportion of cases which follow operations about the upper respiratory tract may be ascribed to the more frequent performance of such operations in recent years. There are, in addition, 19 (9.0 per cent) due to other operations under a general anesthetic, making a total of 136 (64.7 per cent) referable to a previous surgical procedure. The etiologic factors in the remaining 74 (35.2 per cent) are less clear. In 48 (22.9 per cent) the onset was insidious and the cause undetermined. A more stormy onset in 17 (8.1 per cent) suggested pneumonia as a cause, but the evolution and grouping of initial symptoms were consistent with lobar pneumonia in only three instances. The abscess followed an upper respiratory infection in 5 (2.4 per cent).

In this series, 141 (67.1 per cent), or two out of every three cases, occurred under such circumstances as to make it reasonable to assume that

* Read at the Chicago meeting of the American College of Physicians, April 20, 1934

the abscess arose in consequence of access to the lung of infected material from the upper respiratory tract

SPECIAL DIAGNOSTIC MEASURES

Bronchoscopy Examination by this means should be considered in all cases with localized pulmonary suppuration. It is especially indicated when there is evidence of bronchostenosis for the purpose of establishing the presence or absence of a foreign body or tumor. Bronchoscopy was done on 72 cases in the present series. Inflammatory narrowing of a bronchus was thus established in 29 and a congested mucous membrane in 11. It is helpful in certain cases in more accurately localizing the abscess by the determination of the part of the bronchial tree from which pus emerges, but the expulsion of purulent material from one bronchus to another by cough may make it difficult to determine its source. In our experience, the method has not proved of value in the treatment of lung abscess in the absence of foreign body as a cause.

Lipiodol Insufflation Seventeen cases were investigated by means of lipiodol insufflation for the purpose of more accurate localization of the abscess. The number is small, as the site of the process can ordinarily be satisfactorily determined by other means. In nine of the cases, or about one-half, additional information of value was not obtained. There is, however, a small group of cases in which localization by roentgen-ray is uncertain on account of obscuration by the overlying shadow of the heart or the diaphragm. With improvement in roentgen-ray technic and the use of profile films in addition to anteroposterior views, lipiodol is seldom necessary for the localization of lung abscess. It is, however, of great value in the differentiation of lung abscess from bronchiectasis.

PROGNOSIS

Of the 210 cases, 73 (34.8 per cent) completely recovered, in 49 (23.3 per cent) the condition was improved, in 10 (4.7 per cent) the disturbance persists unabated, and 78 (37.1 per cent) died. Of 96 operated cases, 27 (28.1 per cent) recovered, 26 (27.1 per cent) improved, 5 (5.2 per cent) were unimproved and 38 (39.5 per cent) died. Of the 38 deaths following operation, we estimate that in 12 the fatalities were in part at least to be ascribed to the operative interference.

TREATMENT OF LUNG ABSCESS

From our review of the present series, certain comments may be made regarding the treatment. In making a decision regarding the most desirable course to pursue, it should be appreciated that there is a large group of cases in which the indications are on the borderline between conservative measures and surgical interference.

Conservative Treatment It is, in general, best to subject patients with lung abscess to a period of observation and investigation for the purpose of deciding upon the best course to pursue. In adopting an expectant policy and meanwhile using bed rest and postural drainage, it must be kept in mind that there is danger of extension of the suppurative process, of the development of multiple from a single focus, of empyema, of cerebral abscess and of septicemia. But in view of the hazards of surgery and the chance of recovery without radical measures, it, nevertheless, seems desirable first to give a fair trial to the simpler procedures. This regime is, in general, applicable only within the first two to three months of the illness and should be continued only so long as progress is favorable, as indicated by the amount and character of the sputum, the abatement of the toxemia and a diminution of the extent of the process by physical and roentgen-ray examination.

Recovery without Radical Treatment From previous experience, the chance of recovery without resort to operation was estimated at about one in every 10 cases.

In the present series the number of recoveries without resort to pneumothorax or surgery has risen to a considerably higher proportion. Forty-five (21.4 per cent) of the 210 were completely relieved of all indications of abscess. In addition, in seven the returns indicate restoration to health and capacity, but the presence of cough and scanty expectoration without foul odor, make it necessary to place them in a doubtful class. The expectation of relief may thus be estimated for the present series as about one in every five cases.

Information is desirable regarding the factors which may be expected to favor recovery without resort to radical measures and it is, in consequence, of interest to consider this recovered group more in detail, with respect to the (1) exciting causes, (2) previous duration and (3) site of the process.

The exciting causes in the 45 completely recovered cases were the removal of tonsils and adenoids in 21 (46.7 per cent), the extraction of teeth in seven (15.6 per cent), an upper respiratory operation in three (6.6 per cent), other operation under a general anesthetic in four (8.9 per cent), an upper respiratory infection in one (2.2 per cent), and pneumonia in two (4.4 per cent). The abscess was primary in seven (15.6 per cent). The percentage incidences of the various exciting causes correspond so closely in the recovered group and in the series as a whole that the nature of the exciting cause appears not to be of moment in influencing recovery without interference.

A short previous duration is one of the most important factors in favorably modifying the chance of recovery under medical observation. In considering the prospect of recovery in relation to a duration of two months or less in the series as a whole, we find that of 110 cases in this category, 34 (30.9 per cent), or about one in every three cases, recovered without other than conservative treatment. Though the expectation of recovery

without operation is thus largely confined to patients with a short previous duration of the disease, 11 cases recovered after a longer period of illness, including five cases of two to three months', one of four months', one of six and one-half months', three of 11 to 12 months' and one of 18 months' duration. The prospect of spontaneous recovery after a long previous duration is more favorable than analysis of the earlier series seemed to indicate, as in that series none of the cases with a previous duration longer than nine weeks recovered spontaneously.

The site of the process is of moment to the prospect for recovery without interference, and in this as in the previous series, a location at or above the root of the lung is relatively favorable, while lesions below this level are less promising. In general, also, it may be said that the symptoms due to the infection and the extent of the pulmonary process were less marked in the cases recovering without radical measures.

Neoarsphenamine in Treatment In view of the frequency with which neoarsphenamine is used in the treatment of lung abscess or gangrene, it is desirable to obtain more definite information regarding its merits. Fifty-five patients in the series have been treated with neoarsphenamine. Comparison of the results in this group with those in the series as a whole suggests that no favorable effect is to be ascribed to its use. Estimate of the value, if any, of the drug is complicated in a majority of the cases by the variability and, at times, by the length of the previous duration of the condition, before treatment was begun. There are, however, seven cases treated with three or more doses of neoarsphenamine within 13 to 21 days of the onset of the disease. Of these seven cases, two recovered completely and one died under medical care. Two of the remaining four were later subjected to pneumothorax and two to a rib resection and drainage. In the last two mentioned cases, in spite of the institution of treatment in one within 16 days, in the second within three weeks after onset, there was extension of the process by roentgen-ray before operation was done. Neither in the clinical aspects nor in the final results, is there evidence that the administration of neoarsphenamine favorably modified the course of the disease.

COLLAPSE THERAPY

Brilliant results in the application of collapse therapy to the treatment of pulmonary tuberculosis merited the hope of its successful use in the management of lung abscess. The suppurative lesions differ, however, in that drainage is the essential factor in healing, while rest is of paramount importance in recovery from tuberculosis.

Pneumothorax in Treatment Treatment by artificial pneumothorax was attempted in 22 patients, but failed in six because of adhesions. Partial collapse was obtained in four and complete collapse in 12. Of these 16 cases nine may be regarded as failures so far as this method of treatment is concerned, as the patients later came to operation. Of the remaining seven,

one completely recovered, three improved and three died. Thus, in our experience, there are only four cases in which benefit was apparently derived from the treatment and the advantage in this small group is offset by three patients in whom the procedure was certainly or probably harmful. All three developed empyema under the treatment and of the three, two died. Though empyema occasionally complicates untreated abscess, its occurrence after artificial pneumothorax in three of 16 cases suggests that the procedure was largely responsible. In our four favorable cases, improvement or complete recovery might have taken place without resort to artificial pneumothorax. In rare instances, as in one case in the series, the artificial pneumothorax makes it possible to localize an abscess, the site of which is otherwise uncertain.

Artificial pneumothorax has proved disappointing as a therapeutic measure. Its use entails the danger of empyema, which may in turn make surgical measures difficult or impossible.

Phrenic Nerve Operation The induction of diaphragmatic paralysis has been followed by recovery in isolated instances of lung abscess. The procedure would seem theoretically likely to be most serviceable with a lesion at the base, but there is always the possibility that bronchial drainage will be hindered rather than favored by this method. It was used as the sole surgical measure in only two cases in this series. In one instance, a man of 34, with a history of cough and foul sputum amounting to 12 to 15 ounces daily for a year, and a process at the right base, the patient died of hemorrhage about six weeks after the crushing of the right phrenic nerve. In the second case, a man of 58, with an abscess involving the middle and right upper lobes, there was no improvement following a right phrenic nerve operation and the patient committed suicide one and one-half years later.

Thoracoplasty Thoracoplastic collapse therapy may be considered with multiple, diffuse, unilobar or unilateral abscesses of such a previous duration that spontaneous recovery cannot be expected. In adopting this method, it is desirable to exclude cases in which there is a prospect of complete recovery following open drainage or lobectomy. Thoracoplasty has the merit of a relatively low operative mortality and the disadvantage that by this means alleviation rather than cure may be expected. Of 15 cases subjected to thoracoplasty, in three a complete posterior operation was done, for diffuse involvement of the right upper lobe in two, and for involvement of the whole right lung in one. Of these three, the operation resulted in complete recovery in two and improvement in one. A partial thoracoplasty was done on the remaining 12 cases, with removal of parts of the ribs in the neighborhood of the involved regions. The operation involved the upper six ribs posteriorly in five cases, the lower six ribs posteriorly in one case, and the ninth to the eleventh ribs inclusive in one, with complete recovery in one case, improvement in three, lack of improvement in two and death in two. Of four patients subjected to apicolysis, one completely recovered, two improved and one died. In the remaining case operated

upon, the condition remained the same, in spite of both a posterior and an anterior thoracoplasty of the upper six ribs and apicolysis

DRAINAGE OPERATIONS

Drainage of Empyema Complicating Lung Abscess The simplest surgical procedure is drainage of empyema when it occurs. Drainage with or without rib resection for empyema secondary to lung abscess may successfully evacuate the lung abscess. Of 13 cases in this group five recovered, one was improved and seven died.

Surgical Drainage of Lung Abscess Operative interference on the abscess is to be considered after a preliminary trial of rest and postural treatment. Lesions near the chest wall are relatively favorable for surgical drainage. The results are most satisfactory when the abscess is single, but multiple circumscribed lesions may be successfully drained. Diffuse lesions with multiple cavities are in general not suitable for surgical drainage. In recent years the cautery has been used to unroof the abscess cavity. Continuance of foul sputum after operation indicates an undrained pocket. Of 56 cases subjected to open drainage, 16 (28.6 per cent) recovered, 16 (28.6 per cent) were improved, 2 (3.6 per cent) were the same after operation and 22 (39.5 per cent) died.

Cautery Lobectomy In addition to the opening of the abscess, a more extensive operation may be necessary for the removal of necrotic parts of the affected lung. Of eight such cases, two recovered, three were improved and three died. A complete lobectomy was attempted in two patients, in one by means of the cautery and in the other by exteriorization, and both died.

SUMMARY

The importance in etiology of operations about the upper respiratory tract has increased from one out of every three cases (1909–1924) to one out of every two (1924–1932). Though bronchoscopy is helpful in certain cases in accurately localizing the abscess, it has not proved of value in treatment in the absence of foreign body as a cause. Lipiodol is seldom necessary for the localization of lung abscess, but is of great value in the differentiation of lung abscess from bronchiectasis. The expectation of complete recovery from lung abscess under conservative treatment has risen from about one in every 10 cases (1909–1924) to about one in every five (1924–1932). A short previous duration is one of the most important factors in favorably modifying the chance of spontaneous recovery, which may be estimated at about one in every three cases with a duration of two months or less. A small proportion of patients recover under conservative management after the disturbance has lasted from two to 18 months. Mild and inextensive processes situated at or above the lung root are relatively favorable for recovery without interference.

Of therapeutic measures in our experience evidence is lacking that neoarsphenamine favorably modifies the course of the disease. Regarding collapse therapy, artificial pneumothorax has proved disappointing and entails the serious risk of inducing empyema. Thoracoplasty may be used in carefully selected cases and is at times successful. Suppurative pulmonary lesions differ from tuberculosis with respect to the application of collapse therapy in that drainage is an essential factor in promoting healing. Drainage of a complicating empyema may successfully evacuate a pulmonary abscess. Open drainage of lung abscess is indicated in suitable cases after a trial of rest and postural treatment. Partial cautery lobectomy may be necessary for the removal of necrotic parts of the affected lung.

THE NATURE OF PELLAGRA · A CRITIQUE

By JAMES S. McLESTER, F A C P, *Birmingham, Alabama*

IN THE first few years of the present century there suddenly appeared in the Alabama Insane Hospital a new disease of unknown nature, the salient characteristics of which were a violent dermatitis of the exposed parts, sore mouth, profuse diarrhea, grave nervous disturbances, and high mortality. The disorder was recognized finally by Searcy, a member of the resident staff, as identical with the pellagra described in the European literature. The rapid spread throughout the Southeastern states of this new and highly fatal disease excited general interest, and concerted efforts were made to determine its cause. Notable among these, but almost forgotten now, was the work of the Thompson-McFadden Commission which during a period of two years made an intensive study of the inhabitants of six mill villages near Spartanburg, South Carolina. The resulting report not only discussed the relationship of certain foods to pellagra but gave interesting data suggesting the conclusion that pellagra is essentially a house disease and that all of the cases of that area could be traced to one focus. A few years later came the carefully planned work of Goldberger who, starting with the prevalent belief that the disease is due to dietary faults, studied the food habits of those people among whom pellagra most frequently appeared, particularly the inmates of orphanages, asylums and prisons. He was signally successful in eliminating this disease, by means of an improved dietary, from two orphanages and an insane asylum in which it had previously been endemic, but the achievement upon which his conclusions largely were based was the production in a group of convicts fed upon deficient diets, of a disease which he and his associates regarded as pellagra. Goldberger's final conclusion that pellagra is due to a specific dietary fault, lack of vitamin G, is now generally accepted the country over, except, it should be noted, in those areas in which the disease occurs with greatest frequency. There, opinion is divided. There are, therefore, two views as to the nature of pellagra, the one, that it is a specific avitaminosis, the other, that there are operative in its causation factors other than a single dietary deficiency. To present this last view is the object of this report.

Two considerations render the avitaminosis theory difficult of acceptance: first the apparent impossibility of invariably relating pellagra to faulty diet or of correcting the disorder by dietary means, and second its epidemiologic characters. The relationship of pellagra to faulty diet is not always clear. True, most pellagrins are poor and their food habits are grievously at fault, but this is not universally true. Time and again I have seen pellagra in a person of ample means whose table was abundantly supplied with the proper

foods, who was apparently well nourished, and in whose diet no gross fault could be detected. Other physicians report similar observations.

I have been deeply impressed also by the difficulty frequently encountered of effectually influencing the course of pellagra by dietary means. We not infrequently see cases in which a balanced ration rich in the vitamin B complex with an abundance of yeast exerts no effect on the fatal course of the disease. The most satisfactory experience I have had has been with liver, at times it works wonders, but occasionally it, too, is of little or no influence. If we conclude that nutritive failure is the sole cause of pellagra, then we must assume that structural damage of such a permanent nature is done that in many instances restoration of the missing factor is of no avail. In most deficiency diseases, notably in scurvy, and in the polyneuritis of fowls correction of the dietary fault accomplishes promptly beneficial, sometimes graphic, results. Not so in pellagra, the result of treatment is much less certain. (Figures 1 and 2)

FIG 1 Pellagra Hillman Hospital (1920-1933)

The epidemiologic features of pellagra likewise are difficult to reconcile with simple avitaminosis. To those of us who saw this disease when it

AVERAGE DAYS IN HOSPITAL

Fig 2 Pellagra Hillman Hospital (1920-1933)

Fig 3 Pellagra death rates

first appeared, and who have watched its spread, there come questions that are difficult to answer. Why did pellagra come with such extreme suddenness and spread like a prairie fire throughout the Southeastern states? What is the explanation of the wide fluctuations in the incidence of this disease since its first appearance in America, with, at first, an exceedingly high death rate and then, following successive outbreaks, a steady lowering of the mortality? (Figure 3) No parallel changes in the food habits of the people have been observed.

Witness the manner in which pellagra, both as individual cases and in epidemic form, seems to spread from definite foci, whether the focus be a single house, a county or a state (Figure 4). The data of the Thompson-McFadden Commission indicate that, among people of the same economic status, the hazard of developing pellagra is greatest, vastly so in a house which has harbored a previous case, less in the house next door, and least of all in houses at a distance. Likewise, statistics show that in Alabama the disease has been much more prevalent in neighboring counties (figure 5), and that in the Southeastern part of the country it has been more prevalent in contiguous states (Figure 6). Why did this disease exhibit itself in its most violent form among the crowded inmates of orphanages, insane hospitals and prisons? There was no sudden change in the dietary habits of the population, nor were the rations of the affected institutions radically different from what they always were. The Alabama Insane Hospital, for instance, has always maintained large farms and its food supply, which includes milk, vegetables and meat, has remained essentially the same for the past 50 years. Why was pellagra epidemic from 1905 to 1909 in the insane hospitals of Alabama, Georgia and South Carolina, while, during that same period, no case appeared in St. Elizabeth's at Washington or in the insane hospitals of New York state? The food of all of these asylums North and South, according to the investigations of Partlow, Superintendent of the Alabama Institution, was not essentially different. These features of the epidemiology of pellagra remind one of such communicable diseases as influenza, measles and smallpox rather than of a true deficiency disease.

The experiments of Goldberger and Wheeler were well planned and admirably executed, but examination of their data permits one to question, I feel, the accuracy of their conclusions. Eleven volunteer convicts were given a grossly deficient diet and upon the appearance of certain skin lesions in six of these the diagnosis of pellagra was made. These six men developed a dermatitis upon the scrotum which Dr. Goldberger and the associated dermatologists accepted as evidence of pellagra. Except in two instances, one a dermatitis upon the dorsum of the hands, and the other an erythema of the neck, there was no eruption on the exposed areas. A recognized characteristic of the skin lesion of pellagra is that it comes first, and as a rule solely, upon the exposed parts, notably the forehead, the front of the neck and the dorsum of the hands, and that these lesions appear most quickly and in most violent form when the patient is exposed to the direct

FIG. 4 Location of domestic incident cases per 10,000

The black columns indicate the incidence of new cases of pellagra among persons living in the same house with a preëxisting case. The columns striped vertically indicate the incidence in the population living next door. The columns striped obliquely indicate the incidence in the population living within the respective village, but farther away than next door from a preëxisting case of pellagra. (Reprinted from Siler, Garrison and McNeal,¹ by permission of the Archives of Internal Medicine.)

Hospital in Birmingham, in only one was a genital lesion recorded and this was not the primary skin manifestation. Goldberger told of a few cases exhibiting scrotal lesions quoted from South Africa and of two in America, in addition to certain subsequent observations made by his associate Dr Wheeler, but he adds, "it remains a fact, however, that the genital lesion whether early or late is a somewhat unusual one." Our experience in Alabama is that it is an extremely unusual one. It is inconceivable to me that these men, working as they were, in the fields of a Mississippi plantation under a midsummer sun should have developed their first lesion on a protected part such as the scrotum, and (except in two instances) shown no lesion whatever upon those parts of the skin exposed to the direct rays of

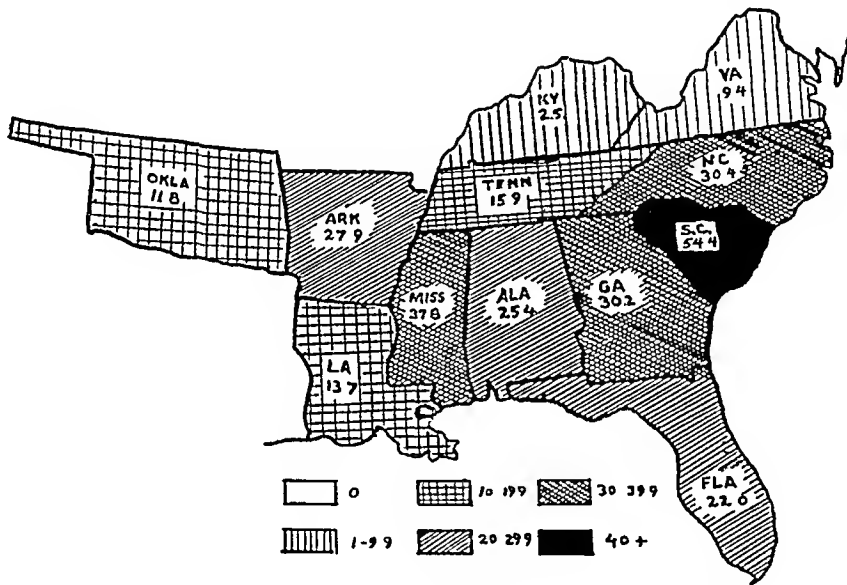

FIG 6 Pellagra death rate (1929) per 100,000 population

the sun. The subjects of this experiment, as the report would indicate, experienced the ill effects of a grossly lacking diet, but that they had pellagra is, I believe, open to reasonable doubt.

The work of Goldberger and his associates has been of inestimable value in demonstrating that faulty diet plays a part in the production of pellagra and in pointing the way toward improvement. I am voicing the opinion, of many observant physicians, however, notably those of the hospital in which pellagra has been studied longest, when I express the belief that the true nature of this disease has not yet been fully explained and that a re-examination of the entire problem would be profitable. Unquestionably nutritional failure plays a part, for most cases, though not all, are associated with faulty diet and most patients, though not all, get well when properly fed, but the assumption that a single dietary fault is the cause of the disease is far from satisfactory.

What, then, are the possibilities? Two, in the order of their prominence, come immediately to mind. First, that pellagra is the expression of a multiple food deficiency, this could be the result simply of a grossly deficient diet or of some physiologic defect which prevents the proper utilization of food, or indeed, of a combination of the two. Second, that directly or indirectly, an infective agent is concerned in its causation. I do not regard as entirely disproved the belief that pellagra is due to nutritional failure plus the invasion of a specific microorganism. The former conceivably could prepare the way for the latter. The high mortality when the population was first attacked and the gradual lessening in severity, accord with our experience in epidemics of infectious disease, and, since pellagra appears to be a house disease, if we accept tentatively the infectious theory, then there is much which would suggest that this infection is carried by an intermediate host. An infectious nature would explain its sudden appearance and rapid spread, while necessity for a vector would explain its appearance most often among conditions under which personal cleanliness is difficult and in institutions in which over-crowding is the rule.

Such considerations incline me to the belief, notwithstanding the careful work that has gone before, that the last word regarding the nature of pellagra is yet to be said.

THE RECENT TREND TOWARD A DIFFERENTIATION BETWEEN ALLERGY AND IMMUNITY, AND THE RELATIONSHIP TO CLINICAL MEDICINE *

By LAY MARTIN, M D , F A C P , *Baltimore, Maryland*

FOR many years writers have been promulgating the idea that allergy is an integral and essential part of the process of immunity. It has been taught and almost universally believed that the local and general response of allergy has been a necessary, although at times, a dangerous defense reaction in the immunological mechanism. In the past few years a small number of men have questioned this belief and their queries have led to investigations, the results of which point strongly to the idea that allergy and immunity can be dissociated and that the former is not necessary for the proper functioning of the latter.

The object of this paper is to develop the theoretical and investigative facets of the subject and to present to the clinician what is an extremely important, but as yet insufficiently accentuated, problem in medicine.

In medical literature it would be difficult to find more confusion than that which obtains in the interpretation of such terms as allergy, anaphylaxis, hypersensitivity and immunization. At the onset it will be necessary to make clear what meaning and usage will be made of these words in the following exposition.

Allergy is used to represent that delayed reaction which follows the reception into tissues of an antigen to which the tissues are sensitized. It is characterized by edema, inflammation, tissue destruction and necrosis. It is typified by the tuberculin reaction of Koch and the Arthus phenomenon.

Anaphylaxis is used to describe that immediate reaction which takes place in smooth muscle when its sensitized cells come in contact with the antigen to which they are sensitized. It is entirely different in action from the allergic reaction described above and may take place in the water bath by the Schultz-Dale method after all the blood has been removed through perfusion. In the intact animal it is typified by the acute shock of a guinea pig sensitized to a protein, which has received intravenously a small dose of the specific antigen. The most striking pathologic change is found in the marked distention of the lungs brought about by the spasm of the small bronchiolar musculature, tissue necrosis does not occur.

Hypersensitivity (or hypersensitiveness) is used to express that state of an animal which is allergic or anaphylactic or both. As will be shown below, both states may exist in the same animal and it may be possible temporarily to remove one and leave the other intact. It should only be used as a

descriptive term when it is not necessary to designate in more detail the type of sensitization

Immunization is the word which has done most to cloud the issue. It has been loosely used to describe a number of procedures and of states produced by such procedures. It will be used here to describe the process of making an animal resistant to bacterial invasion or to the effects of bacterial toxin. An immunized animal is one which can withstand bacteria or toxic products which would greatly distress or kill a control animal. It is not used to represent that state which causes an animal to react with dangerous smooth muscular spasm, or inflammation and tissue destruction, to bacteria or a foreign soluble protein, which are non-toxic to normal animals but to which it is sensitized. As the subject is desperately in need of clarification, further discussion, in the hope of simplification, seems permissible.

The early investigators of the effects of diphtheria toxin and toxoid showed that animals could be made immune by injecting the filtrate in gradually increasing amounts. At an early stage substances appeared in the blood stream which neutralized the toxin in measurable amounts. These protective substances were called antitoxins or immune bodies. When toxin was injected into animals properly immunized no reaction occurred and the animals appeared undisturbed.

It was also found that the injection into animals of materials, such as egg white and foreign sera, promoted the production of antibodies which reacted, *in vitro*, with their specific antigens and neutralized them in a way analogous to the toxin-antitoxin combination. The reaction within the animal in this case (when the antigen and antibody united) was not the quiet, harmless union of the diphtheria toxin-antitoxin but an explosive, dramatic affair which more often than not killed the sensitized animal. As antibodies were produced after both the bacterial toxin and the non-toxic protein were injected and as both gave similar test tube reactions, they were both looked upon as immune bodies. That they reacted within the intact animal in different ways was quite evident but both reactions were looked upon as the results of immunization. It was held that the reaction of humoral antibody with the antigen was the method by which the cells were protected against the protein coming in contact with them and causing even greater damage. To call an occurrence such as that which takes place when an innocuous material, egg white, penetrates into the body, an immune reaction is sardonic humor indeed. These animals are not immune they are hypersensitive. At this time it is of interest to recall a portion of the excellent investigation of Neill, Sugg and Richardson¹. They have observed that if guinea pigs are repeatedly injected with diphtheria toxin or toxoid they not only develop such antibodies as antitoxin but that after they have been Schick negative for varying periods of time they become hypersensitive. At this time an intravenous injection of the toxoid will produce anaphylactic shock. In animals which have been injected in the usual

manner, no such reaction occurs. It is apparent that these animals were immunized against toxin and later became hypersensitive. To say that they became hypersensitive to the protein of the toxin and not to the toxin itself would seem to beg the question as it is quite probable that these are one and the same thing. These men succeeded in desensitizing some of the hypersensitive animals and their immunity to the toxin remained.

This discussion of anaphylaxis and immunity is perhaps somewhat apart from the main topic, namely the dissociation of allergy and immunity, but it is included as it is quite possible that both forms of hypersensitivity represent responses to a fundamental change in the animal's mechanism.

The difference between the methods of production of the hypersensitive states, anaphylaxis and allergy, is a point of interest. Some investigators find that after intracutaneous injections of bacterial protein or bacteria, they are able to demonstrate allergy but not anaphylaxis, others find that both reactions will occur. Following the intravenous injection of the same materials some investigators find only the anaphylactic response, others see both. The variable in this rather unsatisfactory state of affairs seems to be the dosage and repetition of dosage, of the sensitizing agent. At the present time it appears that when a small dose is given repeatedly, intracutaneously or intravenously, there will be produced respectively an allergic or an anaphylactic type of response. The question is, however, not satisfactorily answered and awaits further investigation. Tables 1 and 2 are included because they indicate the data presented in some of the more recent publications. Study of them will show that there are at least a few points remaining to be clarified.

Robert Koch² made the observation that if the tuberculous animal was reinjected with tubercle bacilli a local response developed which was evidenced by edema, inflammation, necrosis and ulcer formation with final healing. The same was true if tuberculin was injected instead of the virulent organisms with the exception that there was rarely ulcer formation. The reaction was a delayed one and reached its culmination in 24 to 48 hours. It came to be known as the *tuberculin reaction* or Koch phenomenon. Von Piquet³ became greatly interested and referred to it as allergy (meaning altered tissue reactivity). Subsequently a great many investigations were undertaken and through the excellent demonstrations of Romer,⁴ Baldwin,⁵ Krause⁶ and numerous others, it became widely believed that the tuberculin reaction was to be found only in the presence of a tubercle brought about by infection. Later it was demonstrated by Petroff and Stewart⁷ that a sufficient dose of dead tubercle bacilli given parenterally would produce the same result.

It has also been abundantly shown that in those instances in which there was both infection and allergy the animal was completely resistant to reinfection. Later it was shown that resistance to reinfection and allergy was found after inoculation with heat-killed bacteria and also with an avirulent strain isolated by Trudeau, called R₁.

Krause and numbers of other experienced workers have become convinced that the allergy which accompanies infection is one of the strongest protective weapons at the command of the body. This is the widely known statement, "We believe that specific tubercle immunity occurs through a fixation of germs that result from the operation of the allergic reaction"⁶ He believed with Baldwin "The inflammatory reaction following inoculations of immune animals is the important thing. We are justly entitled to the opinion that cell accumulations about the bacilli are performing the duty of dissolving them or retarding their growth"⁵ This theory was strengthened by the investigations of Willis⁸ who found that in the normal animal, bacteria left the field of inoculation in a matter of minutes and could be demonstrated in the regional lymph glands in a few hours. In the infected (allergic) animals no organisms were found in the glands until several days had elapsed. This work has recently been corroborated by Freund⁹ and

complements the observations of Koch who noticed that the regional lymph glands of the reinfected animal did not become enlarged. Along the same line it is important to report the investigations of Opie¹⁰. He was able to show that none of the egg white, which was injected into the skin of an animal sensitized to it, reached the blood stream, but all was precipitated in the localized Arthus reaction. He believed that the precipitate acted as an irritant and caused the inflammation. This is quite different from the conception of Krause, who believes that the inflammation is a direct result of the union of antigen and sensitized cells.

Coming from such excellent sources the idea gained credence that the allergy found in any bacterial disease is part of the defense reaction of the

body Among others, Tsuda,¹¹ Cannon and Pacheco¹² and Menkin¹³ have published studies which have added to the weight of this belief Tsuda states that if specific organisms are injected into sensitized tissue and "if immunity is sufficiently enhanced, the injected cocci at the injected site show the phenomenon of agglutination in the form of follicular clumps and aggregations of microorganisms" He also states that the injected bacteria showed such evidences of degenerative change as swelling, poor staining, and inequality in size This work was extended by Cannon and Pacheco who found that staphylococci injected into specifically sensitized skin areas tended to agglutinate and clump more readily than in normal animals They believed that this was helped by the inflammatory reaction and in this they tended to agree with Menkin He believes that it is due to the inflammatory reactions—specific or non-specific—that a barrier is formed and bacteria are held at the seat of inoculation From his studies he gained the impression that there is an increased permeability of capillaries in areas of inflammation and that the lymphatics in such fields become obstructed He demonstrated that foreign particles, when injected intravenously, tend to accumulate in these areas and that if they are injected locally, they are held there He believes that the increased capillary permeability is the reason for the first finding, and the obstructed lymphatics for the second His work is excellent but in dealing with the question of antigen in sensitized tissue (allergic reaction) his theories are open to question A typical allergic reaction does not become fully developed until a few hours after inoculation and it cannot be this delayed reaction which is holding the antigen in check, for in the normal animal, as Willis⁸ has shown, the dispersal of bacteria takes place in a matter of minutes What occurs to hold bacteria there in the immune animal is an important point in the differentiation of allergy and immunity If it is not allergy, what is it? Before trying to answer this question other conditions must be considered

As is shown above there is considerable evidence that the allergic response is found in close association with immunity and there is, furthermore, much evidence which might incline one to believe that the reaction is an integral part of immunity However, in spite of this apparent union there is no proof that in the immune allergic animal the later reaction is essential to the immunological processes, that is, that the edema, inflammation and tissue destruction are essential and that immunity cannot exist in the absence of allergy

There are a number of observations which cause one to point an accusing finger at the untoward results of allergic reaction and regard it as a dangerous and perhaps unnecessary companion It is commonly accepted that many of the characteristics of disease entities are based on hypersensitive phenomena Pleurisy and pericarditis in tuberculosis are commonly accredited to hypersensitivity and there is much evidence that the establishment of this sensitization sets the stage for the development of meningitis and generalized miliary tuberculosis following ulceration of foci in the same

disease There is evidence that pneumonia develops in animals which have been sensitized to bacteria and soluble proteins (Sharp and Blake,¹⁴ Fried¹⁵) This has been shown either following intratracheal injection of pneumococcus autolysate into rabbits sensitized with pneumococci or by direct pulmonary injection of horse serum into rabbits specifically sensitized It is quite possible that tuberculous pneumonia is an allergic reaction There is much favorable criticism of the idea that the rash of scarlet fever, the joint involvements in rheumatic fever and the glomerular nephritis associated with lymphoid disease, are the result of allergic reaction It seems quite likely that the intestinal hemorrhages of typhoid fever are brought about by the action of specific antigen on the sensitized lymphatic tissue In fact, in the whole gamut of diseases it is possible to point out destructive lesions and frequently fatal terminations which are quite probably the result of allergic response Therefore, it would seem of essential importance to attempt an investigation, planned to demonstrate conclusively whether allergy is an integral part of immunity and if not, whether the animal can recover from infection more easily and promptly in its absence

Bouquet and Negre¹⁶ in 1928 presented the case for the French investigators in tuberculosis and stated "Immunité et hypersensibilité sont donc deux états distincts et indépendants des organismes infectés par le bacille de Koch"

Arnold Rich¹⁷ was the first clearly to analyze the situation and he has set a standard of excellence and ingenuity in investigation which will be difficult to surpass At the onset it should be stated that immunity to various bacteria has been established in a number of species of animal by MacKenzie,¹⁸ Zinsser,¹¹ Swift,²⁰ Julianelle,²¹ Tillett,²² Goodner,²³ Bull and McKee,²⁴ Rich²⁵ and numerous others Practically any method which permits sufficient numbers of virulent or heat-killed organisms to penetrate the skin will produce immunity As noted above, allergy or anaphylaxis or both almost always appear at the same time

Calmette⁻⁶ was much criticized in his immunological attempts with BCG because after a certain period his inoculated children and animals, which had previously been reactive, became refractive to tuberculin skin tests, that is, possessed no demonstrable allergy He was, however, able to show that in spite of this reprehensible deficiency, as it was called by those of the allergy-being-an-essential-part-of-immunity school, his animals were immune to reinfection There is still acrimonious discussion concerning the proof of the immunity in children MacKenzie¹⁸ in 1925 noticed that as he gave rabbits repeated intraperitoneal injections of heat-killed and later virulent pneumococci, his animals became anaphylactic and immune, but even with repeated injections they did not develop antibodies and there was no skin reactivity to the nucleoprotein of pneumococcus He found that the serum of these rabbits would when injected intravenously into normal rabbits protect the latter against many lethal doses of the pneumococcus, this protection was transferred without the accompaniment of allergy In a

later publication he reported some studies on the effects of repeated skin inoculations of pneumococcus nucleoprotein in rabbits. For about 10 to 14 days the animals became skin reactive but whether they were or were not allergic, their resistance to infection was no different from normals. Julianelle²¹ subsequently showed that continued skin activity could be obtained by and to the pneumococcus nucleoprotein but that there was no immunity.

This was indeed an important series of observations for it showed that in the anaphylactic, non-allergic animal there was immunity and further that allergy against pneumococcus proteins was not associated with immunity. Nevertheless, much remained to be done to prove the dissociation of allergy and immunity.

Willis has for years been in agreement with Krause in his belief in the protective nature of allergy. In 1928 he reported²⁷ that guinea pigs which had been infected two or three years previously with a strain of avirulent human tubercle bacilli (R_1) did not react allergically, as they had done previously, either to tuberculin or virulent H_{37} . They were, however, immune. He made no comment that this was, at least, an indication that allergy was not essential to immunity.

Among the first of the series of experiments noted above, Rich and Brown²⁵ in 1930 enlarged upon the investigations of MacKenzie. Rabbits were repeatedly injected by vein with large doses of heat-killed organisms, these animals became allergic and immune. It was possible passively to transfer this immunity to rabbits but it was not possible to demonstrate any transfer of allergy. In fact it is very difficult passively to transfer allergy to bacteria although it may be done with bacterial protein products. That same year Branch and Cuff²⁸ published their observation and among other conclusions stated that "allergy and anaphylaxis in tuberculosis are independent phenomena and immunity may be present without allergy."

In the next few years equally important studies were reported. Clawson²⁹ compared animals made allergic by repeated intracutaneous injections of heat-killed streptococci with those receiving the same dosage intravenously. The former became allergic, the latter did not. The allergic animals were slower in removing virulent intravenously injected organisms from the blood stream than the non-allergic. Furthermore, at the end of two hours there were more streptococci in the livers of the former group than in those of the latter. He felt that the allergic state did not in any way prevent the spread of disease and that the non-allergic animals had a better chance of recovery.

For a number of years, Florence Seibert³⁰ has been carrying out a succession of excellently conceived studies on the purification of the tuberculin protein and has finally obtained it in a very pure state. With it she has been able to disprove many of the old tenets on the relation of allergy to immunity, especially in tuberculosis. It was not through lack of trying that allergic responses were not obtained after repeated injections of old tuberculin into animals. It had been tried so often and so diligently that

"no tubercle, no allergy" was a common phrase. By repeated intracutaneous or intravenous injections of tuberculo-protein, in dosages in which the nitrogen content was equal to the amount of egg white nitrogen used in the routine sensitization of animals, she was able to establish in her animals a high grade of allergy which could be passively transferred. In addition to this she found that the allergic animals were not more resistant to inoculation with virulent tubercle bacilli than normals. Sabin and her co-workers³¹ corroborated this within a short time, more demonstrations that the allergic response per se is not a valuable protective mechanism.

As it was essential to show that animals which had been both immune and allergic would remain immune after the ability to respond allergically was removed, Rich and Jennings³² carried out a very ingenious and clear cut experiment. It is important to recall that those who insist that allergy is an integral portion of immunity, say that it is through the edema, inflammation and tissue destruction produced at the point of entrance of virulent organisms that the bacilli are halted and immobilized until they can be destroyed or ejected. Consequently, if it can be shown in an immune animal, in the absence of edema, inflammation and tissue destruction, that the injected virulent organisms remained grouped at the point of entrance one's belief in the necessity and benefit of allergic reactions would be at least shaken. Rich and Jennings were able to do this. Rabbits were made highly allergic and immune by repeated intracutaneous injections of heat-killed pneumococci. One-half of the animals were desensitized by the intravenous injection of a large dose of the same vaccine, they were thus rendered immune and non-allergic. These two groups as well as a group of controls received intradermally a virulent suspension of the same bacteria. That which was expected took place: the normal animals (controls) reacted with a typical inflammation which spread over a large skin area, the immune-allergic animals reacted with greater intensity than the controls and the lesions broke down with ulcer formation, the immune-non-allergic animals showed little if any reaction and recovered from the infection fully as well as the immune-allergic ones.

It is in the microscopic sections in this series of animals that a great deal of interest centers³³. In the controls there was a rapid spread of individual bacteria throughout the tissues. On the other hand in both the immune-allergic and immune-non-allergic groups, the organisms tended to remain in clumps as though agglutinated. Although the clumps slowly enlarged in diameter there was no distribution of individual organisms through the tissues. One is led to believe that the action of immune antibodies and not the altered tissue reaction (allergy) is the phenomenon which prevents the spread of organisms through the body.

The investigations of Rothschild, Friedenwald and Bernstein³⁴ add weight to the observation given above and have a more direct application to the human. They infected a large group of guinea pigs with an R₁ strain of tubercle bacilli: an organism which has been satisfactorily shown

to confer immunity When allergy was well established these investigators began to inject the test animals with minute but steadily increasing doses of tuberculin After a period it was possible to give them, without reaction, 10 mg of tuberculin, a dose of sufficient magnitude to kill the untreated infected animals This dose the normal controls tolerated without demonstrable damage At this time the three groups were infected intradermally with a virulent human tubercle bacillus, H_2 - The results were quite conclusive The local lesion in the untreated control appeared after some days as a small nodule In the untreated, but R_1 infected animal, a typical tuberculin reaction appeared, reached its full size in 48 hours, and healed after ulcer formation In the desensitized animals there appeared but a small nodule, no greater than that in the controls, but no evidence of specific tissue reactivity The control animals became riddled with tubercles, both the desensitized and the untreated R_1 infected animals possessed good immunity As the desensitizing injections were continued during the six weeks the animals were observed, there is strong evidence that continued lack of allergic response in no degree hindered the immunological process of the animals In fact, the desensitized animals suffered less for they did not sacrifice tissue through a sloughing ulcer as did the allergic ones

It has been mentioned above that the proponents of the belief that allergy is of essential importance state that the main protective service of the inflammatory reaction is to restrict the movement of bacteria and to prevent their dissemination Numerous investigators^{44 45 46, 47} have shown that although edema is the first change seen in the reacting allergic area, this is soon followed by an influx of polymorphonuclear leukocytes and later by monocytes It is their idea that the outpouring of leukocytes is important in forming a barrier to prevent the migration of the foreign material This subject has been clarified by Rich and McKee³⁰ as follows After animals were made immune and allergic, sufficient benzol was given them to remove most of their circulating leukocytes, then virulent pneumococci were injected intradermally into these animals and into a group of normal controls In the control animals the typical inflammatory reaction took place and the invading organisms were surrounded by leukocytes, in the test animals, there was no outpouring of leukocytes or fibrin but the bacteria became closely grouped and remained so Later the animals died as the immune antibodies could not dispose of the invaders without the aid of leukocytes

SUMMARY AND CONCLUSIONS

At this time the investigations bearing on the dissociation of allergy and immunity have abundantly demonstrated certain conditions

- 1 Animals which were once allergic and immune have with the passing of time become non-allergic but have remained immune

- 2 It has been possible actively to immunize an animal without the concomitant production of allergy

3 There is ample proof that although animals have become skin reactive to the bacterial proteins, they have not developed immunity

4 Animals which were allergic and immune have been desensitized without the loss of their immunity

5 It has been possible passively to transfer immunity to animals without making them allergic

6 By almost complete removal of the leukocytes from the blood stream of immune animals, it has been possible to show that these cells are not necessary to hold the specific antigen at the point of entrance

On this basis, one is justified in making the assertion that allergy and immunity are separate reactions and that the former is not necessary for the action of the latter. Because so little work has been done on man, one is not yet justified in categorically stating that it is always wise to remove allergy once it has been acquired, however, the results of the work on animals surely incline one to believe that this may be a good procedure. Equally important to consider is the possibility of actively immunizing individuals without making them hypersensitive.

There is, therefore, opened up a very sensible field for investigation which presents to the clinician the idea that he must seriously consider the establishment of some method of desensitizing the body without decreasing its immunity, tuberculin treatment in the human is an example of this. If the body can be prevented from reacting in an allergic manner, that is, with edema, inflammation and tissue destruction, the infected individual will be spared much discomfort in the course of his disease, and his convalescence may take place more quickly. It may well be that by this means a definite decrease in the mortality from infections will take place, a decrease in that mortality due to the allergic reaction which for years has been considered, without real basis, as an integral portion of immunity.

EARLY RECOGNITION OF MYOCARDIAL DISEASE *

By WALTER L. BIERRING, M D , F A C P , *Des Moines, Iowa*

THE diagnostic signs of myocardial disease may be grouped under two classes first those which are based on morphologic changes with obvious physical symptoms that make a direct appeal to the senses, and second those that are based on functional reactions, entirely subjective in character and often not susceptible to recognition by the human sense organs

In general practice two or possibly three distinct types of heart disease are encountered In childhood and young life the valvular affections prevail, usually the sequel of the acute infectious diseases, principally rheumatic and streptococcic infections which generally attack the valvular endocardium, but may involve the pericardium and myocardium Diphtheria, typhoid and the influenzal group of infections are further etiologic factors The resulting heart disease is recognized mainly by physical signs, subjective phenomena having a minor place in diagnosis

With middle life the effects of syphilis on the cardio-vascular system become more manifest Widening of the aorta area and accentuation of the second aortic tone are significant of the aortitis so common to this form of heart disease

The third type belongs to the aging period in the middle and later decades of life, often noted in the prime of life This form of heart disease is quite a different process, being largely the result of wear and tear with nutritive disturbances affecting principally the cardiac musculature and leading to degenerative changes with replacement fibrosis Its etiology is indefinite and often as obscure as the associated conditions of arteriosclerosis and hypertension Clinically it has no manifest or clear cut physical signs until the later or terminal stages of the process The subjective story is often very suggestive and diagnostic of the condition Distinctive and characteristic clinical pictures have been developed for the several advanced or terminal stages Acute coronary thrombosis is now recognized as a distinct clinical entity, and its prompt diagnosis is of common occurrence Chronic coronary artery disease or coronary sclerosis, likewise permits of ready diagnosis

The clinical evaluation of heart disease of all forms centers more and more around the question of the integrity of the myocardium Myocardial failure or insufficiency of varying degrees is associated with valvular disease and the different forms of chronic heart disease Its symptomatology is familiar and requires no repetition

The clinical onset in the chronic types is often of striking suddenness, occurring in individuals previously in apparently good health, yet in each

* Read at the Chicago meeting of the American College of Physicians, April 19, 1934

condition it is safe to assume the existence of basic anatomic changes in the myocardium that have required a long period, probably years, to develop.

It is in this developmental period that the clinical syndrome of the early stage of myocardial impairment may be detected. Patients passing through this stage comprise rather a large group, they come to the attention particularly of the general practitioner and the dispensary or out-patient clinic, and are seen less frequently in a consulting practice.

It seems unfortunate in some respects that heart diseases have become a highly specialized field of medicine, and to a large extent have been taken out of general practice. Mackenzie¹ always contended that the general practitioner, by reason of his familiarity with the habits and history of the patient, was able to detect the earliest signs of disease.

The phenomena included in this syndrome or grouping of symptoms in early myocardial disease are almost entirely subjective, and perhaps have no definite sequence, yet considered concurrently they present a rather suggestive symptom complex. In a large measure these phenomena are expressive of a lowered myocardial reserve, and as such they have been considered by other observers.

The need of a careful history is evident, and its completeness will depend on the art and ability of the examiner to draw out of the patient the essential subjective complaints. The history should include a careful investigation of previous infections, particularly such as could produce damage of the myocardium, next, information as to the presence of a familial tendency toward diseases of the circulation is important, and, lastly, a definite history as to the various indiscretions of life which tend toward early vascular changes.

The leading symptom of this syndrome is fatigability. Clinicians are in accord that cardiac fatigue is one of the early signs of myocardial weakness. It represents a patient's reaction to effort, and is generally expressed as tiring or fatigue after the ordinary efforts or habits of his vocation and daily order of life.

The complaint is often of a tired feeling in the legs, more noticeable toward the end of the day. Frequently it is stated that he "is not as good as he used to be." Often there is added the element of fear, or disinclination to perform the usual tasks.

Fatigue is a sensation known to everyone and the term is often loosely applied. It may not be realized that its signs and symptoms affect every body tissue—glands, sense organs, and central nervous system, being just as susceptible as the muscles.

As Wiggers,² the physiologist, has aptly stated, functional reactions in disease differ from those in health only in degree, and there are no pathologic processes in disease capable of evolving new types of functional reactions. The physiologic conception is that manifestations of fatigue are direct criteria of an oxygen debt and of the accumulation of lactic acid. The more rapid development of fatigue in heart disease merely signifies a

deficiency on the part of the cardio-respiratory system in meeting the increased demands of muscles during exercise

Expressed in another way, the physiologic ability to respond to exercise without fatigue becomes a direct measure of the compensatory mechanism held in reserve by the heart, that is, the myocardial reserve

The inability of the diseased heart to compensate for this circulatory inefficiency is due to loss of the myocardial reserve. Again it may be said that in heart disease the oxygen debt is incurred with a less amount of work, and lactic acid accumulates more rapidly

It may be assumed that with early changes in the coronary circulation the inefficiency of the heart muscle will be manifested by cardiac fatigue

Circulatory fatigue may show itself in the form of insomnia, which can be grouped among the early signs of lowered myocardial reserve

The mimicry of gastric symptoms in advanced coronary disease is well known, and it is logical that to a lesser degree this occurs in connection with myocardial weakness. These are expressed under the guise of loss of appetite, gaseous distention and a feeling of pressure in the upper part of the abdomen, the chemical and roentgenologic manifestations being negative. Riesman³ has aptly referred to them as gastric masquerades, adding that apparent disease in the upper abdomen often has its seat of origin in the heart

Certain vasomotor disturbances are a definite part of this syndrome, such as vertigo, giddiness, syncope and occasionally convulsions. Again such psychic phenomena are noted as mental haziness, impaired memory, stupor, drowsiness and hallucinations of sight, hearing and smell. It seems well determined that aside from primary disorders of the nervous system or chemical alterations of the blood, cardio-vascular disorders are frequently responsible for the symptoms of dizziness, unconsciousness, and the psychic phenomena previously referred to. The cells of the cerebral cortex are extremely sensitive to any marked diminution of its supply of oxygenated blood even though temporary, and react promptly by the manifestations as stated. These occur often with simple postural changes, as lacing a shoe, bending forward suddenly, or other movements incident to the occupation of the individual

Recent investigations have shown that the metabolism of the brain does not differ greatly from that of other tissues. The rate of lactic acid formation in the brain tissue appears to be higher than that of the body as a whole, and the normal blood flow per gram of brain substance is larger than that for skeletal muscle, heart, liver or spleen. It is not surprising, therefore, that cerebral activity should be seriously affected in conditions of reduced myocardial reserve as well as in advanced stages of decompensation. These somewhat vague phenomena may accompany or usher in that triad of symptoms which Kauffman⁴ has termed the three steps to heart failure: (a) breathlessness, (b) palpitation and (c) substernal discomfort.

Breathlessness is probably the most important feature of this syndrome, but it again requires a fine distinction to determine whether this is a normal physiologic response or a pathologic manifestation. It is important to determine whether the change in functional response to certain effort tests such as climbing stairs, walking up a slight incline, and daily routine duties are phenomena that have not been noticed before. Often the time taken to return to the resting state will be longer and sometimes painful.

Long before the stage of circulatory failure is reached, the patient with heart disease differs apparently from normal persons only in the degree of muscular activity that brings on dyspnea and weakness.

The normal individual is ordinarily not conscious of the vigorous normal movements of the heart, because he has become accustomed to them. The sign of *heart consciousness*, as manifested by flutter, skipping beats, thumping and palpitations, occurring in middle life after a meal or physical effort, should therefore be given careful evaluation. It is specially significant if such symptoms have not been noted previously. When associated with breathlessness and fatigue, heart consciousness becomes an important part of the total syndrome.

The sensation of *substernal discomfort* is the one symptom that most frequently causes the patient to seek medical advice. Like the expression "heart consciousness," it is a sensation that is difficult for the average patient to describe. Some express it better than others. The sensations apparently may extend from a mere feeling of heaviness over the upper part of the chest to the terrible vice-like constriction experienced in certain forms of angina pectoris. Herrick⁵ has referred to the lesser forms of substernal discomfort as a mild type of angina. That it is invariably associated with physical effort still further confirms this relationship.

Substernal discomfort or distress, unlike breathlessness and palpitation, is rarely masked under any other guise. It is localized more frequently to the left than to the right of the upper part of the chest and radiation is uncommon.

While the subjective phenomena constitute the essential part of this syndrome, certain physical or objective signs have an important relation to it. Of these a demonstrable enlargement of the heart has assumed a primal importance in the recognition of early myocardial disease. Christian,⁶ Stroud,⁷ Eyster⁸ and others have given special significance to this symptom. Eyster considers that the differentiation of the enlarged heart from the heart of normal size is the most important single factor in determining the presence or absence of organic heart disease.

The greatly hypertrophied heart in advanced organic disease is easily recognized by the usual methods of physical examination, but there is need for more accurate differentiation of the hearts that are less abnormal and associated with an earlier stage in the pathologic process.

Studies in most of the lower animals have shown that the weight of

the heart is more closely related to the size of the body than is the weight of any other organ with the exception, perhaps, of the brain

An estimation of the cardiac size in man can be made only indirectly by the projection of one or more of the surface planes of the heart. Of the two general methods employed for this purpose topographic percussion, and the roentgen-ray projection, the latter is now considered more objective and accurate

In a series of contributions from 1924 to 1928, Hodges⁹ and Eyster¹⁰ established tables predicting cardiac area and cardiac transverse diameter in the frontal plane from height, weight and age, as criteria for determining the presence or absence of cardiac enlargement. These were adopted in 1931 by the Heart Committee of the New York Tuberculosis and Health Association and are now recommended by the medical departments of many life insurance companies. These tables are now generally regarded as the most accurate standard available, when used with postero-anterior roentgen-ray plates, and this method is considered superior to the use of the cardio-thoracic ratio

While the tendency is to a most complete use of the roentgen-ray in examination of the gastrointestinal tract, it receives much less consideration in cardiac disease, although it is of equal importance. By means of the fluoroscope, orthodiascope, teleroentgenogram and signs of either right or left ventricular preponderance in the electrocardiogram, definite evidence is presented of the degree of cardiac enlargement

The truest estimate of encroachment on myocardial reserve is therefore best arrived at by the determination of cardiac enlargement. The presence of cardiac enlargement is always of potential significance, it may be the earliest physical sign of myocardial impairment. Of minor import are blood pressure changes as the result of physical exertion. These have been variously interpreted. No satisfactory exercise test has yet been devised. An elevation of 20 mm of mercury after one of the customary exercise tests is regarded as a sign of myocardial weakness. A change in the pulse rate after exertion is also regarded as having some diagnostic significance. When the pulse rate requires longer than five minutes to return to the resting figure, it suggests an impairment of myocardial reserve

VENOUS PRESSURE

Recent observations on venous pressure and its more extensive use in clinical examinations suggest that it has a significant relation to the dynamics of the failing heart. Eyster¹¹ reaches the conclusion that venous pressure is clinically an index of cardiac function and that its clinical significance is largely confined to the one condition of impending or present cardiac incompetence. Venous pressure in cardiac insufficiency varies from the upper normal level (100–110 mm) to 300 mm of water or more. The extent of the failure is roughly proportional to the rise, and the clinical

progress of the patient and the prognosis of the condition are largely revealed by the trend of venous pressure. Frequently a change in venous pressure precedes other clinical signs. Cardiac incompetence has been described as that condition in which the venous pressure exceeds the range within which the heart is capable of responding by increased work to an increased venous load.

ELECTROCARDIOGRAPHY

The electrocardiogram in the early stage of myocardial disease has thus far not been regarded as of especial significance. Signs of conduction disturbance and changes in the ventricular complex are most apt to be found. Left axis deviation occurs so frequently in middle and advanced age periods that many observers regard such a sign as normal, yet, on the other hand, interesting studies have been reported by Luten and Grove,¹² and more recently by Hyman and Parsonnet,¹³ that are very suggestive. In observing the development of bundle branch block from the beginning, they noted that the cases showing early left axial deviation with altered T-waves in the first lead later developed into full blown bundle branch block. As more frequent and serial electrocardiographic studies are made, particularly as additional leads will clear up the so-called silent areas, it is reasonable to expect that early changes will be noted that will prove of diagnostic value.

The nosology or description of the diseases of the heart has varied and kept pace with the changing conceptions of the underlying physiologic and pathologic processes.

Various clinical terms have been proposed for the degenerative type of cardiac disease. While chronic myocarditis has been the usual designation, it is not very expressive nor properly related to the existing disease condition.

Christian¹⁴ has proposed the term chronic non-valvular heart disease, yet admitting that it was not entirely satisfactory.

For the syndrome or group of phenomena, subjective and objective, encompassed in the early stages of myocardial impairment, the term myocardosis has been suggested, being first proposed by Riesman¹⁵ in 1926. Hyman and Parsonnet¹⁶ have published several comprehensive articles under this title. It is a generic term signifying myocardial disease and in that sense rather expressive of the condition. Considered separately, each phenomenon occurring in myocardosis is not diagnostic, but taken concurrently they form a clinical picture that permits of ready recognition. The term is mainly expressive of the myocardial reserve of the heart, which is an important factor in the complicated mechanism of the circulation, and it is likewise suggestive of early anatomic changes in the myocardium. The field of early myocardial disease is open for fruitful investigation, and it offers alluring prospects in the study of the various phases and stages of coronary disease now beyond our ken.

The early recognition of myocardial disease entails a considerable responsibility on the attending physician. The public has a greater fear of

heart disease than of any other disease, except cancer or perhaps syphilis. As Herrick¹⁷ has said, it is easy to sow the seed of fear of heart disease. Phobias may be started and neurotic individuals made more neurotic with a consequent lessening of their activities and happiness. Yet the fullest cooperation of the patient is needed if during the early stages any attempt is to be made to curb or combat the relentless progression of the vascular degenerative changes in the heart peculiar to the middle and later decades of life. It is of primal importance that the patient accept the view that the aging process is a physiologic change and does not permit the same activities as in younger years. When the condition clearly indicates an encroachment on the normal myocardial reserve, rest and limitation of activities should be the main essential in outlining a proper regimen of living.

The proper appreciation of the syndrome of early myocardial disease offers the one hope of modifying and possibly controlling the tendency to progressive and more serious myocardial damage, and, above all, it opens up a new field in preventive medicine that is worthy of our best efforts.

STUDIES OF CELL POTENCIES AND SOME RELATIONS TO NEOPLASIA *

By STANLEY P. REIMANN, *Philadelphia, Pennsylvania*

THERE is a timed sequence of three fundamentals concerned in any increase in cell number in multicellular organisms, and these are the processes of proliferation, differentiation and organization. Since they are dynamic processes which proceed in regular but overlapping order at any given stage of growth and development, it is exceedingly difficult to experiment with them in the higher animals, including man. Both observation and experiment are easier in lower animals, and because they are so fundamental and occur in all types of living things, it is justified to study them in any organisms in which the experimental conditions can be simplified. Especially important is it that their dynamics be studied, that each be segregated from the others, that one or the other be interrupted separately at various points, that the time relations be manipulated, and so on.

To make the terms themselves clear, definitions of them can be given as follows. Proliferation is simply the multiplication of cells. Differentiation is the changes in the cells which lead from the more general to the more specific, or at another stage of the process differentiation is the result of that series of changes occurring within the protoplasm of cells which bring them to the point of being able to perform their functions as members of an adult organism. Organization may be defined as the harmonious, co-operative development of cells of various differentiations so that they can function in the frame of a whole organism.

Proliferation is a function common to protoplasm in whatever living thing it is found. Differentiation and organization, on the other hand, lead to the development of the anatomic and functional peculiarities of each individual, species, genus and family. They are, in other words, the processes which lead to the production of a human from a human fertilized ovum, a dog from a dog fertilized ovum, and so on. Obviously, the factors which determine differentiation and organization are contained within cells and come from parents. We might stress further the point that of the two, organization is the more specific, for differentiations in similar directions occur in many unlike organisms as, for instance, both giraffes and humans have epithelial cells, whereas strict specificity, that is, the way epithelial cells and others are arranged, is what determines that a human is built upon human plans.

Another obvious point in the relations between the three processes is that when differentiation and especially organization have occurred to the extent of producing an example of the proper species, proliferation ceases.

* Received for publication June 2, 1934.

From the Lankenau Hospital Research Institute, Philadelphia, Pennsylvania.

Therefore differentiation, and especially organization, are natural inhibitors of proliferation. Still another relation is obvious when we put it in this form: cells cannot differentiate and organize unless they are present. Therefore proliferation is a necessary preliminary to the others. An important deduction is, that if differentiation and organization do not occur, cells continue to proliferate, e.g., in tissue cultures. Also when organization is disturbed as by an injury, proliferation begins to repair the injury and continues until organization again puts a stop to it.

Now the relation to neoplasia can be put in some such wise: the cells of all tumors proliferate, else, of course, they would not grow. The cells of many tumors differentiate, sometimes fairly perfectly, but the cells of no tumors organize normally. Since, therefore, the factors governing differentiation and organization are present within the cells and since tumors often grow in the very same environment in which normal cells are differentiating and organizing, it would seem that the cause of tumors lies in a failure of their differentiating and especially their organizing powers, or potencies, to introduce this term. Shall we say, then, that the cause of the continued growth of tumors is the failure of their cells to differentiate, and especially organize, properly?

The experiments to be described were directed toward the proliferative phase of cell growth and development. This is an extension of the use of the new tool—sulfhydryl. The story of F. S. Hammett's discovery of this sulfhydryl group as a normal, essential chemical stimulus to cell division and his demonstration that partially oxidized derivatives of this group inhibit cell division has been told before. Suffice it to say, that up to the present, cell division in some 40 odd species of animals and plants, including man, has been found responsive. Results obtained with this reduced-partially oxidized sulfur equilibrium can be translated directly in terms of the normal, something which could not be done until it was discovered, and cannot be done when extraneous cell-division stimuli are used such as tar, roentgen-rays, scarlet red and many others.

The experimental material which I will now show consists of the skins of rats, mice and guinea pigs, and the regenerating claws of hermit crabs. Both were subjected to sulfhydryl, the one to simple application to their skins, the other to living in sea water to which sulfhydryl was added. In addition the crabs were subjected to partially-oxidized sulfur, the inhibitor.

The skins of rats, mice and guinea pigs are simpler than those of humans and consist of a few layers of epithelial cells with no regular arrangement of basal layers, spinous cell layers, pigmented layers. A few groups of cells in the middle layers show spinous structure, a few pigmented cells are found and a few are oriented vertically in the basal layers. After application of the sulfhydryl group, the picture changes amazingly. The cells in the basal layer are practically all oriented vertically as a result of their increased mitotic activity, a definite basement membrane appears. A full and complete layer of spinous cells appears, and a layer of pigmented cells

The increased number of epithelial cells comes from the younger, incompletely differentiated cells of the skin. Adult, fully differentiated epithelial cells of the skin are incapable of division.

In all probability, this latter statement can be expanded to the point of declaring that when any cell is completely differentiated it can no longer multiply. Needless to say, this is extraordinarily difficult to prove, if for no other reason than that accurate methods of quantitative measurements of degrees of differentiation of cells are still to be worked out. Among other implications of this statement, however, are these: wherever continuous or interrupted cell multiplication occurs there must be present "spare parts," so to speak, from which the multiplication can begin, and cells in any given organ or part which retain the power of multiplication for whatever reason, physiological increase in number, repair, regeneration, etc., are not fully differentiated. Which, in turn, means that evolution has not ceased. But will anyone say it has?

At any rate this is a specific reason for the previous statement that differentiation and organization are natural inhibitors of proliferation.

To return to the mouse skins, I repeat from Hammett's interpretation of the biological significance of the picture: the stimulation to rapid division results secondarily in an expansion in the rate and degree of the differentiating and organizing potencies of the cells.

If, then, experimental increase in the rate of cell division obtained with a natural stimulus—sulfhydryl—results not in diminished, but in increased differentiation and organization of the cells so stimulated, it follows that increased rate of cell division alone can never lead to malignancy. Something must happen to their differentiating and especially organizing potencies. Incidentally this is why sulfhydryl alone should not produce malignancy.

Suppose the rate of cell division which is normal to any given growth and developmental process be retarded. Hammett has shown with partially-oxidized sulfur groups in a variety of material what happens then. Conversely, when the rate of cell division is retarded, so also are the degrees of differentiation and organization. But at any given time period, comparison of the retarded material with that of the controls shows that the retarded material is identical with the controls of an earlier time. Therefore decreased rate of cell division alone does not lead to malignancy. I use diagrams (published elsewhere) of regenerating hermit crab claws under the influence of sulfhydryl, sulfoxide, and the appropriate controls to illustrate these points.

In 269 regenerating claws which were studied, 44 growth aberrations were found. A study of them by serial section and comparison with the normals allows an answer to another question.

It is obvious that the sequence under discussion, viz., proliferation, differentiation and organization, must be timed properly or an abnormal part will be produced. Will this abnormal part be a neoplasm, or will it,

in the end, organize as best it can, bring proliferation to a stop, and result in merely a growth anomaly? The answer as written in the crab claws is as follows

In some of the claws, breaks in the chitinous envelope, being laid down as the new claw regenerated, opened this barrier to the proliferating cells. They streamed through and produced an unorganized mass. Since sulfhydryl is a specific stimulus to proliferation, all those claws with defects which were exposed to this chemical group developed growths, and all of them were much larger than those which appeared in the controls (75 per cent), or in the retarded, i.e., sulfoxide-treated, specimens (43 per cent). In other claws unorganized growths were found at the tips of the distal segment of the claw. Study of serial sections and of timed specimens showed that differentiation and organization were progressing in addition to the proliferation, but that the timing of these processes was thrown out of gear. There is no doubt that the growths would eventually have ceased proliferating and smoothed out to a bump on the claws.

Several other specimens of special interest were found, such as a hyperchitinous corresponding to hyperkeratosis, and a second regenerate attempting to grow within the stump. In all of these the same phenomena occurred, viz., the potencies of differentiation and organization within the cells attempted expression, even though the time relations were disturbed and the environment was changed. Important to the present consideration is the fact that proliferation was inhibited.

Space forbids further discussion, even though but a very few of the fundamentals involved in these experiments have been touched upon, really they have only been mentioned. One of the many practical applications may be hastily sketched, however. The time factor is often the crux of the situation in the ordinary pathological diagnosis of tissue. In the edges of gastric ulcers, epithelium is often found in the midst of granulation tissue and the question arises. Is this repair or carcinoma? What would have happened if the surgeon had not removed the ulcer when he did? If merely the relative rates of proliferation, differentiation and organization have been shifted, it is not carcinoma. Nor is it carcinoma if the cells ensnared in a different environment are attempting to express the normal potencies of differentiation and organization within them. That much discussed, but quite impractical subject of tumor grading also is more than touched by these considerations.

What then is the distinguishing feature of malignancy? Increasing the rate of cell division does not change these potencies, in fact it allows of more full expression. Decreasing the rate does not cause neoplasia. Facts from which we cannot escape are that the cells of neoplasms differentiate imperfectly and do not organize, even when in the very same environment in which normal cells are accomplishing these processes. Nor is it a fault in timing as even the inexperienced in oncology can testify, and as the experiments discussed above show. Since the potencies of differentiation

and organization are contained within the cells, the fundamental cause of neoplasia must be a change within them

That there are degrees to this change is also evidenced by numerous facts. The better the differentiation of the cells of a tumor, the slower its growth as tumor grading in its statistical application has shown. But this is but in harmony with the biological truism that the less mature an embryo, the more rapid its growth. In other words, malignancy and benignancy of a neoplasm, in the sense of its rate of proliferation, its invasive properties, its autonomy, etc., can be directly correlated with its deviation from the appearance of the structure which normal cells would produce under the same circumstances.

I, as well as others, have been dissatisfied with even the definition of what a neoplasm is, let alone with many of the views on the subject. In summing up, as good a way as any is to do it in the form of a definition. For the time being, and until and unless more knowledge demands its revision, we say that a neoplasm is a mass of cells which arises from and continues to proliferate within an organism as a result of and in direct proportion to their degree of internal qualitative differences from the other cells of the organism with respect to the potencies of differentiation and organization particularly.

EDITORIAL

THE SO-CALLED 'CIRCULATORY HORMONES'

IN the past few years the rôle of the so-called "circulatory hormones" has been an interesting and ever changing one. The first circulatory hormone was described in 1926 by Frey and Kraut¹. They isolated a substance from urine which, on intravenous injection into dogs, caused a fall in the blood pressure (in the systolic more than in the diastolic) and an increase in the amplitude of the heart contractions. This substance was called "kallikrein," later "padutin." They observed the same active substance in the blood except that it occurred in an inactivated form and had to be especially treated to produce the reactions. After the active substance had been found in the blood, they tested, by intravenous injection, fresh extracts of liver, kidney, and spleen and obtained results similar to those which had occurred with extracts of urine and blood.

In 1929 Frey observed that the fluid evacuated from a large pancreatic cyst contained an enormous amount of the active substance. On further investigation on animals he found that, after total extirpation of the pancreas, the amount of active substance in the urine decreased as much as 80 per cent. He concluded from his experiments that the pancreas was the site of formation of the active substance, that it was stored in various other organs and tissues, and that it was excreted in the urine. Extracts of pancreatic tissue were found to contain considerable amounts of the active substance. Frey used the urine extract kallikrein, or padutin, for his clinical work, however, and injected it intramuscularly rather than intravenously. The physiologic action was believed to produce vasodilatation and, when injected in the rabbit, dilation of capillaries in the ear was observed. Frey felt that this action was not due to the presence of histamine and choline.

Gley and Kisthonos,² in 1929, working in France, prepared an insulin-free pancreatic-tissue extract which they injected intravenously into rabbits. They found that it produced a transitory fall in blood pressure, had vasodilator properties, antagonized the action of epinephrine, and that these effects were not due to choline, histamine, or peptones. This extract may be identical with the circulatory hormone of Frey and Kraut. Standardization of the extract was on the basis of hypotensive units per cubic centimeter. A unit was considered to be the amount of extract necessary to produce barely perceptible evidence of a drop in blood pressure on the tracing when the substance was injected into the jugular vein of a rabbit weighing 2 kg. Wolff, Findlay, and Dessin³ prepared a pancreatic tissue extract after the

method of Gley and Kisthonos, and they corroborated the latter's findings inasmuch as they found that it caused a primary drop in arterial blood pressure when injected intravenously, slowed the heart rate, and antagonized the action of epinephrine.

After intramuscular injection both the padutin of Frey and Kraut and the pancreatic tissue extract were found to give favorable results, particularly in the treatment of cases of angina pectoris. Frey further noted improvement in cases of essential hypertension and in vascular disease, especially in cases in which intermittent claudication was present. He attributed the beneficial results to the vasodilator effects of the extract. Wolff, Findlay, and Dessin used the pancreatic tissue extract among patients with angina pectoris and reported clinical relief in 55 per cent of cases.

Subsequently, Wolff, in collaboration with the Sharpe and Dohme laboratories, made a new, standard, pancreatic tissue extract in which 1 unit would neutralize the pressor effect on anesthetized dogs of 0.001 mg. of epinephrine. His change in the standardization followed the work of Levine, Ernstine, and Jacobson, in which they demonstrated that, by subcutaneous injection of patients suffering from angina pectoris with 1 cc. of a 1:1000 solution of epinephrine, an anginal attack could be induced, whereas no such attack could be produced among normal control subjects. Wolff reasoned that, if epinephrine injected into certain patients subject to angina pectoris would produce an attack, and if a certain vasodilator obtained from the pancreas moderated the action, the favorable results obtained in treatment might be explained by the ability of the tissue extract to neutralize epinephrine. No further standardization of the pancreatic tissue extract has been made.

Up to this time the development of circulatory hormones had been concerned with lowering of the blood pressure, vasodilator properties, and neutralizing the effects of epinephrine. In 1930 J. S. Schwartzmann⁴ prepared an extract from skeletal muscle. He assumed that some sort of antispastic substance was at work during the contraction of active, skeletal muscle. The fact was known that anginal pain sometimes disappeared if the patient continued his muscular effort. This extract was called "myoston" and it was standardized on the basis of its adenosin phosphoric acid content, each cubic centimeter containing 2.5 mg. This standardization was interesting in view of the previous work of Drury and Szent-Gyorgi, who studied the effect on the mammalian heart of extracts of heart muscle, brain, kidney, and spleen, and who found a definite and transient effect on the heart. They isolated the substance which they felt was responsible for the reactions, and from its chemical properties they believed it to be adenylic acid or adenosin phosphoric acid. They found also, that adenosin prepared from yeast nucleic acid had an action identical with that of adenylic acid. They intravenously injected into animals both the tissue

⁴ SCHWARTZMANN, J. S. Muscle extract in the treatment of angina pectoris and intermittent claudication, *Brit. Med. J.*, 1930, 1, 855-856.

adenylic acid and the adenosin, and they observed a lowering of the blood pressure which they thought was due to the slowing of the heart rate and to general arterial dilatation

In contrast to these observations Nuzum and Elliott reported that, following intravenous injection of guinea pigs with pancreatic tissue or the Frey "hormone," these substances did not cause a transitory, complete heart block, a supposedly specific test for adenylic acid and adenosin Wolff, however, noted that 250 micromilligrams of adenosin phosphoric acid corresponded in activity to 1 cc of pancreatic tissue extract It is still impossible to say what the common active substance is

Myoston, on intramuscular injection, gave excellent results in cases of angina pectoris, as reported by J S Schwartzmann, and M S Schwartzmann treated a few patients with intermittent claudication very successfully Myoston has also been prepared for oral administration, but its effect is more transient and, at present, adequate dosage would be almost prohibitive in price

More recently, excellent results have been reported by clinicians of The Mayo Clinic⁶ with the use of pancreatic tissue extract, myoston, muscle adenosin phosphoric acid and adenosin, administered intramuscularly to patients with occlusive disease of the peripheral arteries in whom claudication was the major complaint To evaluate these extracts more accurately, these workers described a standard test for quantitating claudication Injections of known vasodilating agents were made before the extracts were administered without effecting a significant change in tolerance to exercise Following intramuscular administration of the extracts, a sharp increase in the amount of exercise was possible, which persisted for days

Up to this time the beneficial results have been attributed by various workers to the vasodilator action, but later workers have shown that the improvement bore no relationship to dilation, as measured by standard methods Pancreatic extract and myoston do not cause a rise in skin temperature or an increase in the rate of heat elimination from a limb It was thought that the action was probably a direct one on the muscle, supplying a deficient substance or neutralizing an accumulated metabolite in the presence of anoxemia of the muscle Dietrich and Schwiegk have shown that in animals coronary flow is increased by these extracts Their use in coronary disease may prove beneficial and they may thus in the future have a wide clinical application

REVIEWS

Diseases Peculiar to Civilized Man By GEORGE CRILL, M D xi + 427 pages, 15 x 32 cm The Macmillan Company, New York 1931 Price, \$5 00

This book is an exposition of the theory of its author that hyperthyroidism, neuro-circulatory asthenia, peptic ulcer, and possibly other diseases, are due primarily to the stress and strain of civilization. He calls them "kinetic diseases," and believes them due to an abnormally high sustained activity of the adrenal-sympathetic-thyroid system, or of some of its component parts. Several persons have contributed sections on specialized topics. A section of the book is devoted to a description of certain surgical methods, particularly denervation of the adrenal, and operative procedures upon the sympathetic. Over one-half of the book is given over to detailed case histories. There is a fair bibliography.

This work gives a very readable account of an interesting and superficially plausible theory. The claims made as to the beneficial effects of adrenal denervation are certainly broad. An effort is made to include diabetes in the list of kinetic disorders, and the author makes the flat statement (page 155) that "in a small group of cases, adrenal denervation has abated or cured diabetes." He also believes that the same procedure "abates or cures peptic ulcer." He seems to have established, to his own satisfaction, that bilateral denervation of the adrenals does not cause chronic adrenal insufficiency in man. As he states, the recuperative power of the adrenals is very great.

The accounts of the cases of acute adrenal insufficiency following denervation are of great interest, especially Case 1, page 124. It seems probable that this constitutes an instance of the true experimental production of Addison's disease. Following bilateral denervation of the adrenals, the patient ran a six weeks' course with asthenia, increasing pigmentation, hypotension, and increased concentration of blood non-protein nitrogen (urea). Autopsy indicated degeneration of both adrenals, which was considered secondary to thrombosis and obliteration of the blood vessels.

It seems unnecessary to dwell, in view of the present state of our knowledge, upon the potential dangers which certainly attend any surgical interference with the adrenal glands, and in hands lacking the technical skill of the author of this book, such dangers will doubtless be very much increased.

A Textbook of Medicine By 141 American authors, Edited by RUSSELL L. CECIL, A B, M D, Sc D, and FOSTER KENNEDY, M D, FRSE. Third Edition. xi + 1664 pages, 18 x 25 cm. W B Saunders Company, Philadelphia 1933. Price, \$9 00.

In his preface to this work, the Editor states "In order that physicians and students might have the benefit of an authoritative and up-to-date treatise on every medical subject, it seemed desirable to prepare a textbook of medicine in which each disease, or group of diseases, would be discussed by a writer particularly interested in that subject. This book represents an effort to carry out such a plan." The appearance of the third edition, six years after the first, indicates that the plan has been very successful, and examination of the book reveals the causes of its popularity.

One hundred and thirty well known writers have contributed articles. Though one feels at times that there may have been too much division of labor, the description

of different phases of a subject by various writers is usually managed with coherence in plan and similarity in style of presentation. Thus the section on tuberculosis is divided into seven parts and contributed by five authors. Uniformity in style and quality of their work, however, makes this section a very well organized unit. Certainly in the section on diseases of the kidney, the articles on anomalies of urinary secretion, uremia, and nephritis, would be much better correlated if they were contributed by one author instead of by three, as differences in terminology used may be somewhat confusing to students. This difficulty has been partially obviated by including, in the article on nephritis, Christian's recently published table indicating the terminology of no less than ten different classifications of Bright's disease in common use. This should help the student to a better understanding of this frequently confusing subject.

Any attempt to list even a few of the contributors would be useless, as it would simply consist in calling the roll of many of the most prominent American teachers, all of whom are eminently qualified to discuss the presented subjects.

Generally, the minor criticisms that might be offered are greatly outweighed by the evident good qualities of the book. The articles are uniformly well written, clear, interesting, up-to-date, and with few exceptions, unusually well correlated.

The size and broad scope of the volume make it impossible to review any more detailed account of its contents. Certainly, it may be recommended to students as a modern and complete textbook.

Clio Medica: Medicine in Persia. By CYRIL ELGOOD, M.D. 105 pages, 11 x 17 cm.
Paul B. Hoeber, Inc., New York City. 1934. Price, \$1.50.

By this time this series of handy little volumes on medical history ought to be pretty well known to the profession. Everyone interested in medicine in any of its aspects should own these books which can be put in the pocket and read while waiting for any reason, and it is an unusual doctor who does not have spare minutes which are usually wasted. The author of this latest addition was at one time physician to the British Legation in Teheran and had ample time to study the history of one of the most interesting countries on the globe. The land of Scheherezade and Omar Khayyam, of Rhazes and Avicenna, Ismail and Haly Abbas, where 'Jamshid gloried and drank deep,' has a fascinating history beginning indeed with that legendary hero, for as Firdausi puts it:

Jamshid thus spent
Another fifty years and did much good
He introduced the scents that men enjoy,
As camphor, genuine musk, gum Benjamin,
Sweet aloe, ambergris, and bright rose-water
Next leechcraft and the healing of the sick,
The means of health, the cause of maladies,
Were secrets opened by Jamshid.

Health and disease in early Persia were gifts of the gods and thus it seems that the inhabitants did not let it go entirely at that for in the there is the record of an early section the use of an Elgood quotes as follows:

His birth
So wilieth
A blue-steel
Because the

Her pain and fear, then let him ply his craft
 And take the lion from its lair by piercing
 Her waist while all unconscious Then imbruing
 Her side in blood, stitch up the gash
 Put trouble, fear, and care aside, and bruise
 With milk and musk a herb that I will show thee,
 And dry them in the shade Dress and anoint
 Rudaba's wound, and watch her come to life

When Alexander the Great (whose medical history has recently been written by an Italian) went to Persia, Firdausi relates, that an Indian rajah gave him four gifts a girl, a philosopher, a magic cup and a physician

A youthful leech who diagnoseth
 Disease by making an uroscopy,
 So long as he is at the court, the Shah
 Will never ail

We go through the Seleucid and Sassanid ages, the Caliphate and Baghdad school, with Rhazes and Avicenna and Ismail, the great medical trinity of the day, if we may speak of a couple of centuries as a day The later history is not so brilliant, the Caliphate decayed and the Mongol and Safavid dynasties ruled, then the Qajar dynasty lasted until 1926, when Reza Khan became ruler starting the Pahlevi dynasty A fascinating story condensed in scarcely more than a hundred pages

L'Exploration Clinique Medicale-Technique et Semeiologie Published under the direction of ÉMILL SERGENT, Professor of the Faculty of Medicine of Paris Sections by him and nine collaborators Paper, two volumes, 1165 pages Masson and Company, Paris 1934 Price, 120 francs

In 1913 Sergent published the first edition of his *Traite Élémentaire d'Exploration Clinique Medicale* Five editions followed quickly, with translations into Italian, Spanish and Roumanian The treatise was both a guide to the student and a stimulus to the teacher Now after a lapse of years Sergent brings up to date the newer knowledge of the technic of medical examination and the signs of disease

The two volumes comprise sections on The Respiratory Apparatus, by Émile Sergent, The Circulatory Apparatus, by Camille Lian, The Nervous System, by Paul George, The Sympathetic Nervous System, by René Mignot, Radioscopie and Radiography of the Thorax, by Pierre Pruvost, Radiography of the Nervous System, by Pruvost, Examination of the Abdomen, by R d'Heucqueville, Examination of the Digestive Tract, by d'Heucqueville, Laboratory Methods Applicable to Diseases of the Digestive Tract, by Pierre Oury, Examination of the Spleen, by d'Heucqueville, The Liver and Hepatic Function, by Ribadeau-Dumas, The Pancreas, by Bordet, Kidneys and Urinary Function, by Ribadeau-Dumas, Analysis of Urine, by René Hazard, Examination of the Blood, by Pruvost and Bordet, Elementary Laboratory Methods, by Pruvost, Radiology of the Abdomen, Extremities and Vertebral Column, by Pruvost

The volumes are well printed, with numerous excellent plates and illustrations There is a good index This new edition of a very popular earlier work will no doubt serve the same useful purpose as its predecessor and will meet with approval It has been edited with much care and gives due credit to work done outside of France

W B S

The Science of Radiology Edited by ORTO GLASSER, Ph D, of the Cleveland Clinic Foundation 311 + 450 pages, 17 5 x 25 cm Charles C Thomas Springfield 1933 Price, \$4 50

This is a much needed and timely book, sponsored by the First American Congress of Radiology The editor, Otto Glasser, is well qualified by virtue of his extensive experience in Europe and America in the physics of radiology, and also through his close contact with its clinical applications The contributors are all outstanding men, occupying high positions as physicists or clinicians

The book depicts "the outstanding features developed in the science of radiology from the time of Roentgen's discovery, to the period of this congress" (First American Congress of Radiology) The various chapters are written by men particularly adapted to the given phase they treat The space is well allocated to the various aspects of radiology, including history, physics and all branches of medicine affected The correlation of x-ray and radium therapy which are inseparable in clinical application, is well brought out,—a valuable feature in a treatise of this character The full bibliography adds value to the book as a work of reference It is so interestingly written that it reads almost like fiction, yet it includes a vast amount of information

G E W

The Doctor and Citizenship By THURMAN D KITCHIN 89 pages, 14 x 20 5 cm Christopher Publishing House, Boston 1934 Price, \$1 50

Dr Kitchin practiced medicine for some years and then was made Dean of the Medical School of Wake Forest College and more recently he was chosen as president of the College His book consists of ten articles, partly addresses and partly essays, mostly about medicine and citizenship and kindred topics He stresses the fact that to be a good doctor the physician must be a good citizen as well It may best be described by quoting one of the running heads of the accompanying advertising leaflet, "An inspiring book of medical culture" That tells the story

J R

The Medical Profession and the Public (A collection of ten papers) 112 pages American Academy of Political and Social Science, Philadelphia 1934 Price, \$1 00

This symposium, presented at a joint meeting of the College of Physicians of Philadelphia and the American Academy of Political and Social Science in Philadelphia, February 7, 1934, discusses the whole subject of the physician's relation to the public The problem from the physician's standpoint is discussed by Drs Nathan B Van Etten, Henry E Sigerist, Grant Fleming, Roger I Lee Morris Fishbein, and Thomas Parran, Jr The sociological side of the question was discussed by the following Messrs James H S Bossard, Edgar Sidenstricker, Michael M Davis and William T Foster

Throughout the symposium the reader will find a good many stimulating comments, many of which he may not agree with The first speaker emphasizes the trend toward socialized medicine While in general this is the stand taken by the lay speakers the physicians on the program took a position against it The last speaker emphasizes What the public does demand is the right to say not how medicine shall be practiced but how it shall be purchased and paid for and who has a better right than those who do the paying? In any event, it is folly to burden physicians any longer with business affairs which they have notoriously mismanaged, and for which they are not trained in which they are not interested and which interfere with that single-hearted devotion to patients which is the glory of their profession"

Fishbein, as the last speaker for the medical profession, states "It is conceivable that out of many of the experiments that have been made and are being made, out of the scientific advancement of medicine itself, there may be a greater and greater tendency toward discounting individuality in medical care. The medical profession feels that the sick man is still an individual, a human being. It has shown repeatedly its willingness to work with economists, sociologists and statesmen toward schemes for making such individual medical care feasible for the vast majority of our people."

COLLEGE NEWS NOTES

Acknowledgment of the following gifts to the College Library of publications by members is herewith made

Dr Walter L Bierring (Fellow), Des Moines, Iowa—one reprint,
Dr John M Dyson (Associate), Hazelton, Pa—one reprint,
Dr Dunne W Kirby (Associate), Philadelphia, Pa—6 reprints,
Dr Samuel A Shelburne (Associate), Dallas, Texas—5 reprints

Dr Warfield T Longcope (Fellow), Baltimore, Md, has been elected a member of the board of scientific directors of the Rockefeller Institute for Medical Research, succeeding the late Dr William H Welch

Dr Walter L Bierring (Fellow), Des Moines, Iowa, Dr Benjamin H Orndoff (Fellow), Chicago, Ill, and Dr Cyrus C Sturgis (Fellow), Ann Arbor, Mich, are among the distinguished guest speakers on the program of the Omaha Mid-West Clinical Society at its annual assembly in Omaha, October 29 to November 2

At the tenth annual meeting of the American Association of the History of Medicine, held some months ago in Cleveland, the following Fellows of the College were elected as indicated

Dr E B Krumbhaar, Philadelphia, Pa, *President*,
Dr W S Middleton, Madison, Wis, *Vice-President*,
Dr E J G Beardsley, Philadelphia, Pa, *Secretary-Treasurer*,
Dr Carl V Weller, Ann Arbor, Mich, *Member of the Council*

Dr J Gurney Taylor (Fellow), Milwaukee, Wis, has been appointed Chairman of the newly organized subsidiary board for Part III of the National Board of Medical Examiners

Dr Virgil H Cornell (Fellow), Curator of the Army Medical Museum, has been reelected Secretary of the National Institute of Health for the coming year

Dr S A Slater (Fellow) Worthington, Minn, has been elected President of the Southern Minnesota Medical Association for the forthcoming year. Dr Charles W Mayo, Rochester Minn was elected First Vice-President, Dr J C Michael, Minneapolis Minn Second Vice-President, and Dr H C Haben (Fellow), Rochester, Minn, Secretary

Dr Burton R Corbns (Fellow), Grand Rapids, Mich became Acting Secretary of the Michigan State Medical Society on September 1, 1934

Dr Virgil P Sydenstricker (Fellow), Augusta, Ga, gave the lecture on the "Treatment of the Anemias" in connection with the series of lectures at Sandersville, Ga, sponsored during the past summer by Emory University and University of Georgia under the supervision of the State Board of Health

Dr Wallace M Yater (Fellow), Washington, D C, has been elected Vice-President of the Washington Heart Association

Drs Arthur C Christie (Fellow), J Russell Verbrycke, Jr (Fellow) Thomas A Groover (Fellow), and Henry C Macatee (Fellow) are among those who will serve upon the District of Columbia Health and Hospital Council composed of representatives of the medical, dental and civic societies as recently organized under the sponsorship of the Council of Social Agencies. Ross Garrett, Health Secretary of the Council of Social Agencies, has announced that this newly organized Health and Hospital Council "will be available to all government authority as a medium of ascertaining opinion and reaction of the majority in professional, administrative and lay organizations representing the citizens in the district"

Dr Joseph A Mendelson (Associate) has been retired from active service as Major, Medical Corps, U S Army, Station Hospital, Fort F E Warren, Cheyenne Wyo, because of physical disability. He has planned to return to Tientsin, China, to engage in the practice of Internal Medicine

Dr Henry I Klopp (Fellow), Superintendent and Physician in Chief of the Allentown (Pa) State Hospital, became a Life Member of the American College of Physicians on August 20, 1934

Dr Edward Schons (Fellow), St Paul Minn, retiring President of the Minnesota Radiological Society, addressed the joint meeting of the Minnesota Radiological Society and the Minnesota State Medical Association at Duluth, July 16, 1934, on 'The Value of Cholecystography by the Oral Route, with an Analysis of 189 Operated Cases'

On September 1, 1934, Dr H Beckett Lang, heretofore Director of Clinical Psychiatry at the Marcy State Hospital, Marcy, N Y, became Director of Clinical Psychiatry at the Pilgrim State Hospital, Brentwood, Long Island

Dr Daniel F Milam (Fellow) has been transferred to Panama by the International Health Board of the Rockefeller Foundation

Dr James L McCartney (Fellow), who for the past three years has been Psychiatrist and Director of Classification under the New York State Department of Correction at the Elmira Reformatory, resigned from that position September 1, to enter the private practice of neuropsychiatry in Portland, Oregon. Under a grant from the New York Academy of Medicine, Dr McCartney has written a book on the classification of prisoners which is now in press.

A PLAN TO EVALUATE INDEPENDENTLY SEROLOGIC PROCEDURE FOR THE DIAGNOSIS OF SYPHILIS IN THE UNITED STATES

Since the serologic conferences at Copenhagen and Montevideo, there has been an increased interest in the relative value of serologic tests for the diagnosis of syphilis. At these conferences the test of only one serologist of the United States was presented for consideration. There are a number of excellent serologists in this country, many of whom have described original modifications of the complement-fixation and precipitation tests for syphilis. It is felt that the tests of these workers merit consideration.

The United States Public Health Service is cooperating with the American Society of Clinical Pathologists in the drafting of a plan to evaluate independently serologic procedure for the diagnosis of syphilis in this country. Briefly, the plan contemplates the collection of specimens of blood from at least 1,000 individuals and the distribution of comparable specimens to the laboratories of serologists who have described an original modification of a complement-fixation or precipitation test for the diagnosis of syphilis. The donors of the specimens will be carefully selected so as to measure both the specificity and sensitivity of the serologic procedure. The sending of specimens to workers at considerable distance from the point of collection will be expedited by the use of the most modern transportation facilities, while the delivery of specimens to nearby serologists will be delayed so as to make the delivery time approximate that for those workers at the more remote points.

A committee of five members consisting of two specialists in the field of clinical syphilology, two members of the American Society of Clinical Pathologists, and one officer of the United States Public Health Service will organize the plan of study and, after all laboratory reports have been submitted by participating serologists, will interpret the results on the basis of clinical findings. The collection of the specimens will begin about December 1, 1934, and a number of serologists will be invited to take part in the evaluation scheme.

It is possible that the name of some serologist who has described an original modification of a test for syphilis may have been inadvertently omitted. Any serologist desiring to participate will be extended an invitation upon presentation of suitable proof as to the originality of his modification of a serologic test. A brief description of the plan will also be sent to those workers who may be interested.

Correspondence should be addressed to the Surgeon General, United States Public Health Service, Washington, D. C.

OBITUARY

DR JAMES LESTER JUNK

Dr James Lester Junk, of Connellsville, Pa, died May 20, 1934, as the result of a ruptured abdominal aneurysm, after an illness of but a few days. He was 54 years of age, having been born October 3, 1879, at the Junk homestead at Laurel Hill, in Fayette County. After attending grade school, he first entered California State Teacher's College, and, later, Pennsylvania State College. It was at State College that his proficiency at football first began to attract the wide attention which, later, at the University of Pennsylvania, where he studied medicine, won him the signal honor of a place on Walter Camps All-American team of 1905.

Dr Junk graduated from the Medical School of the University of Pennsylvania in 1907, with highest honors, and after serving in a Philadelphia hospital and finishing a postgraduate course at Harvard Medical School, began the practice of his profession at Dunbar, Pa, in 1908, removing after four years to Connellsville.

During the war he held a commission as first lieutenant, and was in charge of the base military hospital at Aberdeen, Maryland. Later he joined the National Guard, and was appointed Major in the Medical Corps in 1922, which rank he held until his death.

Always deeply interested in children and their education, he served for years on the Connellsville Board of Education, holding the office of President for five consecutive years. In 1909 Dr Junk married Miss Janet Handlin, of Dunbar, Pa. Mrs Junk died in 1914. Dr Junk is survived by his mother and four brothers.

He was a past president of the Fayette County Medical Society, and was also a member of the Pennsylvania State Society, of the American Medical Association, and had been an Associate of the American College of Physicians since December 30, 1921. He belonged to the Sigma Alpha Epsilon fraternity and was a Mason.

So high a place did Dr Junk occupy in the regard of his community, both as citizen and physician, that all united to show him honor. His body lay in state in the State Armory, and every medical, fraternal, educational and civic group of that section took action to pay their final respects. Many of the stores of the city closed during the services—all attesting to the deep regard and appreciation in which he was held, and to the sorrow felt at the ending of a life so full of usefulness and devotion to others.

CLINICO-PATHOLOGIC OBSERVATIONS ON INFANTILE PARALYSIS REPORT OF 125 ACUTE CASES WITH SPECIAL REFERENCE TO THE THERAPEUTIC USE OF CONVALESCENT AND ADULT BLOOD TRANSFUSIONS. THE POSSIBLE RELATION OF BLOOD GROUP TO THE SEVERITY OF THE DISEASE*

By D MURRAY COWIE, M D, F A C P, J P PARSONS, M D,
and K LOWENBERG, M D, *Ann Arbor, Michigan*

DURING the Michigan infantile paralysis epidemic of 1931 (figure 1) 125 cases came under our observation. Eighty-one of these were first seen in the so-called systemic or pre-paralytic stage, 44 in the paralytic stage. All of the systemic cases received either convalescent poliomyelitis serum, convalescent whole blood, adult whole blood or a combination of these by the various administration routes. Four of these developed paralysis. One was not under our control and is omitted from the total number, leaving 80 treated cases for analysis. Seventy-seven of these, or 96 per cent, did not develop paralysis. In the three patients developing paralysis the involvement was slight, and recovery was complete at the end of one month of convalescence. No case in this series shows any paralysis today.

Of the paralyzed cases, 27 received immunotherapy as soon as they came under observation. Nine of these (33⅓ per cent) showed definite improvement (three completely recovered), 18 cases (66⅔ per cent) showed no improvement (five died). Seventeen paralyzed cases received no immunotherapy, 12 per cent improved, 89 per cent showed marked residual paralysis.

Criteria upon Which the Diagnosis Was Based Symptoms: Fever, headache, vomiting, diarrhea, constipation, tremor, irritability, drowsiness, sweating, disturbance of breathing and swallowing, dromedary phenomenon. Physical findings: stiff neck, stiff back with or without pain, normal, hyperactive, or lost, tendon cremasteric and abdominal reflexes, spinal fluid

* Presented at the meeting of the American Pediatric Society at Rochester, Minnesota May 1932.

From the Departments of Pediatrics and Infectious Diseases, and Psychiatry, University Hospital, University of Michigan, Ann Arbor, Michigan.

changes (pressure, cell count and cell type, globulin mastic and colloidal gold tests), blood count

Personnel All persons connected with this investigation may be considered to have been expert in the work done by them. That is, those examining spinal fluids had had much experience before assisting in the epidemic. The large majority of the counts were made by one man and checked by several others. Those giving intraspinal injections of serum, blood transfusions, and intravenous glucose had also had much experience with this type of work. Blood typing and cross blood typing were done with great care by experienced workers. The physical examinations were carefully conducted and verified. A member of the Department of Anatomy and Orthopedics made complete and almost daily muscle studies on the large majority of the cases, spending practically his entire time at the Contagious Hospital.

Technic in General The very large majority of treatments were

given in well equipped operating rooms. Most of those patients desiring to remain in their homes were taken to the hospital for their treatments. Those who for some reason could not come to the hospital were cared for at home with scrupulous aseptic technic. A microscope and facilities for blood typing and cross typing were taken to the home.

Cooperation Perhaps more complete cooperation of the entire citizenry of a community than that shown in our immediate vicinity has never been seen. Anticipating an epidemic of magnitude, a conference was called August 20, and the organization known as the Michigan Commission on Infantile Paralysis was formed. The Commission was financed by the State Medical Society \$1,000, the W. K. Kellogg Foundation \$4,500, and the Couzens Children's Fund \$4,500, making a total of \$10,000, the amount estimated necessary to carry out the program. The State was divided into districts, each presided over by a physician chosen by the Commission. Serum was pooled at the State Department of Health and sent to the Commissioners who distributed it free of charge to all indigents and to those who for any reason were unable to pay the otherwise nominal charge. From 460 paid donors, 35,195 c c of serum were produced, and 21,530 c c were distributed. We are indebted to Dr. C. C. Slemons, State Commissioner of Health, for these figures. The Commission cooperated in every way possible, assisting physicians and defraying expenses for careful medical services. There was no citizen in the State deprived of the best medical care procurable.

Educational campaign lectures were given in the various towns and districts. The press cooperated splendidly in keeping the people informed on how to recognize the disease and how to secure proper service. In our own vicinity, the schools were not opened until the epidemic was well under control. The theaters, churches and Sunday Schools admitted no children. The book stores developed a method of school book purchase and distribution that excluded children from their stores. The press gave daily information on the epidemic urging parents to have their children carefully observed for any manifestation of ill health. Physicians and all people interested in public health were in every way cooperative.

There were naturally many cases observed that were not suggestive of poliomyelitis. On the other hand, we saw many cases with fever, digestive upsets, headaches, etc., which on careful watching did not develop the neck and spine signs, but which may have been abortive forms of the disease. No serum was given to these and no record of them is included in this report.

All the information possible was given the public concerning the high incidence of protection afforded by the immunological treatment as reported by various observers. It seemed to us that there was no one in our immediate community who did not have an intelligent idea of the epidemic. Any fear acquired by this knowledge was legitimate. There was little or no panic. On the other hand, there was a certain confidence

that if the disease was recognized early it could be checked or modified by the use of serum. The difference of opinion concerning the value of serum was kept alive by those who did not favor its use. This apparently had no effect in the response of the public to the advice of the Commission.

CLINICAL OBSERVATIONS

GROUP A SYSTEMIC CASES

Analysis of 80 cases treated during the pre-paralytic or so-called systemic stage of the disease

Age The ages varied from 1½ to 45 years. 92½ per cent of the cases were between 1½ and 15 years old.

Fever All the cases showed fever. The temperatures varied from 101° to as high as 105° F. In 22 per cent it was high, in 32 per cent moderate, in 46 per cent slight. It was moderate or slight in 46 per cent, in which group the three cases of paralysis occurred. The dromedary phenomenon was present in 21, or 26 per cent.

Headache Headache was complained of in all but four cases. These patients were too young to complain.

Vomiting Vomiting was present in 43 cases (53 per cent), diarrhea in 12, or 14 per cent, constipation in 26, or 32 per cent.

Tremor Tremor was observed in 13, or 16 per cent. *Irritability* was noted in 8, or 10 per cent, *drowsiness* in 29, or 36 per cent, *sweating* in 19, or 23 per cent, *neck sign* in 74, or 91 per cent, *spine sign* in 79, or 99 per cent. The *reflexes* were hyperactive in 37, or 45.5 per cent, diminished in 5, or 6 per cent, absent in 7, or 8.5 per cent. The *bulbar type* of the disease was seen in 3 patients, or 3.6 per cent. The *spinal type* in 78, or 96 per cent.

The *spinal fluid cell count* was increased in 78, or 96 per cent. Of the three in which counts were not made, one had otherwise marked manifestations and her sister similarly affected had a spinal fluid cell count of 60. One case, a girl of five years, who was exceptionally irritable, showed marked neck and spine signs, all reflexes hyperactive, headache, vomiting, diarrhea, and fever of 102° F. It was thought best not to do a spinal tap on this patient. The third case, a girl of eight, who had unquestioned manifestations, had a sister with similar manifestations whose spinal fluid showed a cell count of 105.

In 53 cases the spinal fluid cell count was done once. The counts in these cases varied between eight and 1200, in only eight cases was the count below 20. Counts were done twice in 16 cases, they varied between four and 350. In two cases counts of four and eight cells, respectively, were found, in each of these globulin was positive. Counts were done three times in four cases. They were as high as 1200 declining to 150, 950 declining to 19, 90 declining to 6, and 207 declining to 22, respectively.

The *spinal fluid globulin* test was positive in 46 cases, and negative in

28 of the 74 cases in which it was done. In 11 of the latter a check observation was made at a subsequent time. The result was the same. Only once was globulin negative when the mastic test was positive, only twice when the colloidal gold test was positive.

The *spinal fluid mastic* test was done in 39 cases. It was positive in eight, negative in 31. The reaction varied from 011000 to 344222.

Treatment Twenty-one cases received immunotherapy as early as the second day, 16 the third day, 17 the fourth day, 12 the fifth and sixth days, seven the seventh and eighth days, four the ninth and tenth days, one the thirteenth day and one on the fifteenth day of the disease. Eighty-six and one-half per cent of the cases in this group received treatment between the second and sixth days of the disease. The three cases in which paralysis occurred were treated on the seventh, second and third days of the disease, respectively. One of these received 50 c c of convalescent whole blood intramuscularly, one was given a transfusion of 125 c c of adult blood, 20 c c of convalescent serum in the muscle and 10 c c in the spine, and one received a transfusion of 175 c c of adult blood and 20 c c of convalescent serum in the vein.

In compliance with the request of the Poliomyelitis Commission most of the cases treated outside the hospital received serum intraspinally or intravenously. Only a few of those treated in the hospital were given serum intraspinally. The dose used intraspinally varied between 6 c c and 20 c c, and was given after preliminary removal of a similar amount of spinal fluid. The intravenous dose varied between 10 c c and 60 c c, the intramuscular dose between 20 c c and 50 c c. Convalescent blood transfusions were given to as many patients as possible. The amount of blood varied between 100 c c and 225 c c. Less than 150 c c was given in three cases only, 200 c c and over in 11 cases. Adult blood transfusions were given in the same amounts. One patient with bulbar symptoms, was given 325 c c of adult blood.

The methods of administration of serum and blood are classified in table 1.

Intravenous glucose, in 20 per cent and 50 per cent solutions, was given in nine cases because of special symptoms, referred to later. The amount varied from 100 c c of the 20 per cent solution to as high as 200 c c of the 50 per cent solution.

The report of the Michigan Commission on Infantile Paralysis⁴⁰ (1931) shows that in a selected group of 233 cases in which *convalescent serum* treatment was given during the pre-paralytic stage, 181, or 76.6 per cent, recovered without developing paralysis, and 52, or 22 per cent, developed paralysis. This is in marked contrast with our series in which 96 per cent recovered without paralysis and 100 per cent developed no permanent palsy. Our series differs in that transfusions of convalescent and adult blood were given in addition to convalescent serum in a large percentage of the cases. This may be responsible for the lower paralysis rate in our series.

TABLE I

Method of Administration of Immunotherapy in the 80 Cases under Complete Control *

| | Cases |
|--|----------|
| Convalescent serum alone in the vein | 13 |
| “ “ “ in the muscle | 5 |
| “ “ in the vein and spine | 9 |
| “ “ in the muscle and spine | 1 |

* Transfusions were given in 48 cases, 60 per cent

It is of interest to record the protocols of the paralyzed cases, including the patient who was not under our complete control. They are as follows

CASE REPORTS

Case 78 Anna W, age 2, was taken ill August 15, 1931, with symptoms suggestive of poliomyelitis. This diagnosis was made before entrance and no details are obtainable. On admission August 21, 1931, six days later, the seventh day of the disease, she did not appear acutely ill. There were none of the usual symptoms except those elicited on physical examination. There were pain and stiffness of the neck and back. The left knee jerk was diminished, the right hyperactive. The spinal fluid cell count was 30, mastic and colloidal gold negative, globulin ++++. She was given 50 c c of convalescent serum intramuscularly.

On the tenth day (August 25), the cell count was 20, mastic 111000, colloidal gold 0111110000, globulin ++++. Between this date and the thirteenth day she developed weakness of the abdominal muscles and paralysis of the left gastrocnemius, dorsal flexors, quadriceps and ham string muscles. She was discharged on the thirty-ninth day, September 28, 1931. There was some residual paralysis of the muscle groups described. This, however, completely cleared up in a short time. We should have transfused this patient. Most of the cases coming in as late or later than this one were given more intensive treatment. On the other hand, there were four cases that received about the same treatment and all of them recovered without the development of paralysis, all had marked symptoms.

Case 79 John D, age 6, was taken ill on August 25, 1931, with severe headache, pain in the neck and back and slight fever. Soon after this he became dizzy and vomited when he sat up. He complained of pain in the temporal region if he raised his arms. The bowels were constipated. Examination was negative except for stiffness of the neck and back and pain in the back on bending forward. The reflexes were hyperactive. He was admitted to the hospital at midnight on this date. The spinal fluid cell count was 1200, mastic negative, colloidal gold 0122100000, globulin negative. He was given 20 c c of convalescent serum intramuscularly, and the following morning 10 c c intraspinally. Three minutes after this he developed acute abdominal pain, screamed, and tossed about the bed. The pulse became weak. Gen

eral cyanosis developed and there was a board-like rigidity of the abdomen, spasticity of the lower extremities and marked priapism. Throughout the attack there was excessive thirst. In 45 minutes the attack was over. Soon after this he was given a 125 c c adult blood transfusion.

The course of the illness was otherwise uneventful until the day of discharge, the twenty-third day of the disease. At this time it was observed that the gait of his right foot was not quite normal. This became normal in the course of a few days. We are unable to determine the date of the palsy. His muscles were carefully examined almost daily. The day of discharge his cell count was still high, being 110, the globulin ++++, mastic 111000, colloidal gold 1122210000. This patient has no residual palsy.

Case 80 James T, age 5, was taken ill about 6 00 a m September 2, 1931, with stiffness of the neck and back, vomiting, severe headache, sweating and constipation. A spinal tap was done. The cell count was 700, globulin ++++. He was given 15 c c of convalescent serum in the spine and 45 c c in the vein at 5 00 p m (second day of disease). We advised giving a blood transfusion and an intravenous glucose injection that night. This was not done. He was brought to the hospital the following morning at 10 00 a m (third day). Orders had been left at the ward to give 50 c c of 50 per cent glucose and a blood transfusion on entrance. This was not done. A neurologic consultant felt that poliomyelitis was not present, and active treatment was not carried out. The patient seemed to be fairly well during the day, but toward night difficulty in swallowing developed. The following morning (fourth day) when we first saw him these symptoms were exaggerated and there was general cyanosis from bulbar involvement. Fifty c c of 50 per cent glucose were given intravenously and he was put in the respirator. He died within a few hours. The autopsy record is presented later.

Because stiffness of the neck and back were the earliest signs observed, it is not at all improbable that there had been symptoms previous to this time (dromedary phenomenon) and that the treatment was given later than recorded above. A brother of this child had been ill a week previously with suspicious signs of poliomyelitis, i e, headache, disinclination to play, and some pain in the neck. The symptoms, however, were ephemeral. The father, a physician, had been taking care of poliomyelitis cases. A purely neurological opinion during the early stage of the disease is of little or no value. If reliance is placed on it, it may be definitely harmful.

This case is omitted from the series of 81 because it was not completely under our control. We cannot say that this patient would have lived had the prescribed treatment been carried out. Two other cases showing bulbar symptoms lived. They were more intensely treated. One of these, number 12, is of special interest (page 529), and is recorded later.

Case 81 Grace C, age 7, was taken ill October 4, 1931, with sore throat and fever, which cleared up the following day. Fifteen hours before admission to the hospital on October 7, the third day of the disease, the temperature rose again. The patient became very restless and irritable. Later she became drowsy and complained of headache and pain in the right side of the body, particularly in the right leg. When the leg was extended she would cry out. There was no stiffness of the neck but the spine was stiff. The reflexes were all hyperactive. A spinal tap showed 4 cells, globulin, mastic and colloidal gold tests were negative. She was given 20 c c of convalescent serum in the vein on entrance and six hours later a transfusion of 175 c c of adult blood.

On the fourth day, October 8, careful examination showed extreme muscle tenderness and some weakness of the quadriceps on the right side. On October 13, the ninth day of the disease, reexamination showed no muscle tenderness, palsy or weakness. In this case the serum was given early. The spinal fluid was negative but the symptoms were marked.

GROUP B PARALYZED CASES TREATED AFTER PARALYSIS DEVELOPED

There are 27 paralyzed cases that were given immunotherapy as soon as possible after entrance. These are summarized in table 3. They are grouped together with special reference to the day of the palsy on which they were treated. *Ten were treated on the first day*, of these two completely recovered, two showed definite improvement with only slight residual palsy, four showed no recovery and two, both bulbar cases, died. *Four were treated on the second day*, of these two definitely improved, showing only slight residual palsy, the other two, marked cases, showed no improvement. *Four were treated on the fourth to the fifth day* of the palsy, one of these completely recovered, one, a bulbar case, showed marked improvement with only a slight residual facial palsy, one showed definite improvement and one showed no improvement. *One case treated on the seventh day* was not benefited. Of the remaining eight cases, treated between the thirteenth and the twenty-ninth days of the paralysis, two bulbar cases died, the others showed no improvement.

Of this entire group, three completely recovered. They were treated on the first to the third day of the palsy. Six were definitely improved. This makes a total of nine cases, definitely improved (33½ per cent).

GROUP C PARALYZED CASES NOT TREATED

There were 17 paralyzed cases that did not receive serum. Two improved (12 per cent). Fifteen (88 per cent) showed marked residual paralysis with little or no recovery after entering the hospital. The ages in this group vary from two to 48 years.

If we compare the paralyzed cases that were treated not later than the fifteenth day of the disease with those not treated at all, thus bringing them into line with a similar division treated in the systemic stage of the disease, we have the following results:

TABLE II

| 23 Treated Paralyzed Cases | | 9 Untreated Paralyzed Cases | |
|----------------------------|-------|-----------------------------|-------|
| Improved | 64.3% | Improved | 28.5% |
| Not improved | 33.7% | Not improved | 71.5% |

Intravenous glucose was used in 20 and 50 per cent solutions in 15 cases for relief of headache, pain, muscle tenderness and particularly for bulbar symptoms. The following case we think illustrates benefit from its use.

CASE REPORT

Case 12 Nelson U, age 8, was taken ill on October 2, 1931. He returned home from school in the afternoon with a severe headache. He had complained of being ill during school hours. He then vomited, complained of pain in the back and neck, and of increasing headache. We saw him at 5 00 p m. We regarded the case as an ordinary case of poliomyelitis. There was characteristic stiffness of the back and neck and the reflexes were hyperactive. At 7 00 p m the clinical picture had changed. The temperature had reached 103°. He was stuporous. A spinal tap showed 35 cells, globulin ++++. He was given 6 c c of convalescent serum into the spine and 30 c c in the vein. He continued to grow worse, the stupor increased, and he became wildly delirious. At times he screamed out with pain apparently in his head. At this time, 10 00 p m, we gave 75 c c of 50 per cent glucose in the vein. Soon after this his delirium was less, he stopped screaming and became quiet. He seemed to fall into a natural sleep but the breathing was not normal. It became very rapid, reaching 60. In a few minutes it became slow, irregular and difficult. There was also difficulty in swallowing. Three hours later, 1 00 a m, October 3, we gave him 150 c c of convalescent whole blood in the vein. Within an hour the situation seemed improved but the breathing difficulty still gave us concern. Two hours later generalized convulsions, rigidity and opisthotonos developed. Ten minims of adrenalin were given at this time for fear that allergy might be playing a part in the reaction. This was followed in a few minutes by 50 c c of 50 per cent glucose. The patient relaxed for a while but in a very short time relapsed into convulsions and became cyanotic. We brought him to the Contagious Hospital at this time. His temperature was 104° F, pulse 140, respirations 40. He was given 50 c c of 50 per cent glucose in the vein, 1/8 gr morphine and 1/200 gr atropine sulphate. The convulsions ceased in an hour's time, and at 8 00 a m he was rational. He made an uneventful recovery.

It is our impression that the intravenous glucose (87 grams) was largely responsible for the beneficial results in this case which showed marked manifestations of bulbar involvement. One must also consider the osmotic pull of the blood transfusion as an auxiliary to the glucose. The serum was given early. It did not prevent the occurrence of severe bulbar symptoms. Bulbar manifestations were present at the time the convalescent blood transfusion was given.

We had two quite severe reactions following the use of intraspinal serum. The one just recorded, and case 79. In all, 26 cases received serum by this route. The subject is discussed later.

The Possible Relation of Blood Group to the Severity of the Disease
We have records of the blood type or group in 22 pre-paralytic cases and in 19 paralytic cases. The Moss numerical system of notation is employed in the University Hospital (Groups I, II, III, IV), corresponding to the O, B, A, and AB groups, respectively. Of 130 donors, mostly University students, 27 per cent fell in Group I, 35.8 per cent in Group II, 10.5 per cent in Group III, and 51 per cent in Group IV.

Of the 22 pre-paralytic cases, there were 11, or 50 per cent, in Group IV (AB), six, or 27 per cent, in Group III (A), four, or 18 per cent, in Group II (B), and one, or 4.5 per cent, in Group I (O).

Of the 19 paralytic cases there were five, or 26 per cent, in Group IV (AB), three, or 15.7 per cent, in Group III (A), 10, or 52 per cent, in Group II (B), and one, or 5.26 per cent, in Group I (O).

It is of interest, even though the number of cases is small, to note that of the mild or pre-paralytic cases by far the greatest number fall in Group IV, and 77 per cent of them in the combined Groups IV and III, while of the severe or paralyzed cases by far the greatest number fall in Groups I and II (57 per cent). Setting these figures side by side the comparison is better seen.

Mild poliomyelitis, pre-paralytic—77 per cent, Groups IV and III

Severe poliomyelitis, paralytic—57 per cent, Groups II and I

While we have no right to come to a definite conclusion, it is suggestive from these observations that blood Groups IV and III are the most favorable groups and that blood Groups II and I are the most unfavorable, that is, an individual having a Group II or Group I blood may be more likely to have a severe poliomyelitis than an individual with a Group IV or Group III blood.

Our attention is called to the interesting observations of Jungeblut³⁰ on blood group neutralizing power in poliomyelitis cases. Our results seem at variance with his. Further observations in progress may throw more light on this subject.

PATHOLOGICAL OBSERVATIONS

Acute Cases

Case 80 (James T.) We were able to secure only a small section of tissue from the thoracic cord in this case of marked bulbar poliomyelitis, the clinical history of which has been given earlier.

The gray substance was completely destroyed, containing but a few scattered ganglion cell remains. The nervous tissue was flooded by Hortega elements, astrocytes, lymphocytes and occasional plasma cells, but no leukocytes were present (Figure 1). Countless neuronophagias indicated graves of parenchyma elements. Small foci of necrosis were frequent. The blood vessel system was greatly involved and there were numerous small inflammatory foci in the white matter. There was a pronounced acute meningitis.

Case 86 Virgil P., a seven year old boy, came to the Hospital on what was considered to be the third day of the disease. Inquiry leads us to believe that the prodromal phenomenon was present in this case as there was evidence of indefinite symptoms several days previously. On admittance there was moderate fever, drowsiness, breathing and swallowing difficulty, absence of right biceps reflex and a spinal fluid cell count of 2,300. The diagnosis of bulbar poliomyelitis was made. The patient received 150 c.c. adult blood and 300 c.c. 50 per cent glucose intravenously. He died on the first day in the Hospital.

Brain The leptomeninges are thin and smooth but their blood vessels are enormously dilated and injected. The leptomeninges are bright red in color. Basal vessels are delicate. On frontal sections gray matter is of normal width, of a bluish pink color and the vessels are injected. White matter contains numerous blood points (hyperemia). It is slightly pinkish. The basal ganglia are distinctly outlined and of the same color and appearance as the gray matter. There is a particularly distinct injection of the blood vessels in the medial nuclei of both thalami. A similar condition can be seen in the substantia nigra. All gray nuclei of the subthalamic region, pons and medulla are of a pinkish color, their vessels being dilated and injected. The ventricles are narrow and the ependyma is smooth. There is a small hemorrhage in the pons near the floor of the fourth ventricle.

The leptomeninges of the spinal cord are of the same appearance as those of the cerebrum. The gray matter of the entire cord is very well outlined and distinctly red in color. The white matter is hyperemic.

Spinal Cord The leptomeninges contain numerous lymphocytes and occasional leukocytes and are somewhat edematous. The inflammation affects the perivascular spaces of the blood vessels of the white matter. The infiltration can be followed up to the gray matter. The white matter itself is edematous and contains fairly numerous foci of proliferated astrocytes and occasional lymphocytes. (Figure 2)

In the gray matter the anterior horns are severely affected, numerous ganglion elements are destroyed by neuronophagia and the remaining ones show different acute toxic changes. The gray matter is flooded with countless Hortega elements and

FIG 2 Multiple neuronophagia in both anterior and lateral horns. Parenchyma entirely destroyed. Blood vessels surrounded by dense infiltrates. Marked infiltration of the meninges in the fissura mediana. Microphotograph / 10. Nissl stain.

astrocytes and the blood vessels are surrounded by dense infiltrates. (Figures 2 and 3)

The inflammation extends also over the posterior and lateral horns in many areas so that the entire gray matter appears to be transformed into a single inflammatory focus.

The affection is not always symmetrical, the one side being frequently less affected than the other.

The distribution of the disease process in the different segments of the spinal cord varies considerably, the thoracic and cervical regions being more severely affected

FIG 3 Multiple neuronophagia in the left anterior horn. Right anterior horn better preserved. Pronounced meningitis and perivascular infiltration in the white matter. Microphotograph $\times 10$. Nissl stain.

than the lumbar. In no segment was the gray matter affected in its continuity and the character of the inflammation was a spotty one.

Medulla and Brain Stem. The affection of the medulla and of the brain stem was studied in sections cut through certain gray nuclei.

At the level of the pyramidal decussation, the histological picture was the same as that observed in different segments of the spinal cord.

On section through the midpart of the olives numerous gray nuclei were found to be affected. Particularly severe was the inflammation in the respiratory area (substantia reticularis), but various other nuclei especially those of the cranial nerves (at this level, nucleus nervi hypoglossi and nucleus ambiguus vagi) were also affected.

The nucleus olivaris inferior remained free; its parenchyma was well preserved. There was no glia activity but a few blood vessels of this nucleus were surrounded by lymphocytic infiltrations. The same condition prevailed in the nucleus olivaris accessorius medialis and dorsalis.

On the level of the entry of the acoustic nerve a similar picture prevailed. There were numerous inflammatory foci in the corpus restiformis, the substantia reticularis and nucleus nervi vestibularis were uniformly involved, the olives again remained free.

Higher up the nuclei nervi facialis and nervi abducens were both affected. The substantia reticularis represented a very active area of inflammation, but the nuclei pontis were altogether spared.

On section through the nucleus nervi trigemini the floor of the fourth ventricle contained countless inflammatory foci, the peak of the inflammation being in the nucleus of this nerve and in the substantia reticularis.

The inflammation could be traced through the entire central gray substance surrounding the aqueduct and in the lateral fields of the substantia reticularis

The intensity of the inflammation subsided somewhat in the lower parts of the corpora quadrigemina, the nucleus nervi trochlearis and the stratum griseum centrale being moderately affected

In the region of the roots of the nervi oculomotorii inflammatory phenomena were seen in a number of formations in the nucleus of this nerve, in the substantia nigra, in the red nuclei, and in the central gray substance. The intensity of the inflammation was moderate

The corpora geniculata lateralia were entirely free at this level but the pedunculi cerebri contained numerous infiltrates, a few thrombosed vessels were surrounded by small hemorrhages

In the hypothalamic region occasional scattered inflammatory foci were present, but the disease flared up again in the thalamus where there were numerous areas of intense inflammation

The pallidum, putamen and caudate nuclei, the cortex and the entire white substance of both hemispheres were free of pathological changes, but the meninges showed pronounced inflammatory phenomena at the base of the brain as well as over both convexities

In all regions examined not all gray areas were affected and in those involved the degree of the inflammation varied greatly at different levels. The distribution of the inflammation in the spinal cord and brain stem was not continuous. It was spotty in character, but the histological character was the same throughout

CASE AUTOPSY SUMMARY

Central Nervous System The inflammation involves the meninges, the gray matter of the spinal cord and brain hemispheres but spares the white and gray substances of the brain

The gray substance of the spinal cord, the brain stem, the walls and the floor of the third ventricle and the thalamus are involved in the disease. It cannot be said that the intensity of the inflammation is subsiding in the brain stem, in spite of the fact that certain nuclei of this region were only moderately involved, since it flares up again in the thalamus

Histologically the disease is characterized by the digestion of parenchyma elements by neuronophagia, intense glia response with formation of astrocytes and Hortega elements and severe generalized involvement of the blood vessel system which is surrounded by dense masses of lymphocytes

Thymus Large, measures 11 by 6 by 2 cm. It consists wholly of lymphoid tissue with the thoracic and cervical lobes well represented. Marked hyperplasia of cortex and medulla. Congestion. Extensive hemorrhage into capsule. *Bronchial Glands* Moderately hyperplastic and show moderate anthracosis. *Cervical Lymph Nodes* Not examined. *Spleen* Measures 10 by 5½ by 2½ cm. Weighs 250 grams. Capsule is rather lax and slightly wrinkled. Section shows abundant lymphoid tissue. Cut surface is red in color. The follicles can be seen with the naked eye. No tubercles. Acute passive congestion. Moderate lymphoid hyperplasia. Lymphoid exhaustion. *Large Intestine* Lymphoid follicles rather prominent. No ulceration. *Small Intestine* Very large and prominent Peyer's patches. No ulceration. No tubercles found in the mucosa. Lymphoid tissue hyperplastic. Congestion. In the lower ileum there is marked catarrh of the mucosa. *Appendix* Lymphoid hyperplasia. *Mesenteric Lymph Nodes* Marked hyperplasia. Three mesenteric lymph nodes near the attachment of the mesentery are almost completely replaced by calcified necrotic material. Congestion. Lymphoid hyperplasia. *Left Adrenal* Marked hypoplasia of cortex and medulla. Right same. (C. V. Weller)

Pathological Diagnosis Acute polioencephalitis Asphyxiative death Petechial hemorrhages beneath epicardium, in the thymic capsule and in the gastric mucosa Pulmonary atelectasis and emphysema Acute purulent bronchitis and early bronchopneumonia Acute passive congestion of all organs Subendocardial fatty degenerative infiltration Thymico-lymphatic constitution (hyperplastic thymus, generalized lymphoid hyperplasia with lymphoid exhaustion, hypoplasia of adrenals and aorta)

In the summary of the general pathology in this and succeeding autopsy records, detailed data of the lymphatic and lymphoid structures only are given Somewhat recently attention has been focused on these structures It should be noted here and will be discussed later that these findings form a familiar picture of the status thymico-lymphaticus

Case 90 Thomas M, 14 year old boy, entered the hospital on the fourth day of the disease and the first day of the palsy His symptoms were moderate fever, headache, vomiting, drowsiness, marked neck signs, positive spine sign, normal knee jerks, hyperactive right biceps reflex The spinal fluid showed 99 cells, globulin three plus, mastic 211000, gold 0122100000 There was marked breathing and swallowing difficulty Diagnosis, bulbar type of poliomyelitis Blood Group IV Thirty cc of convalescent serum were given intramuscularly and a transfusion of 250 cc of convalescent blood, and 200 cc of 50 per cent glucose at a subsequent time There was no abatement of the symptoms

AUTOPSY

Brain The leptomeninges are thin, bright red in color, with strongly injected vessels The convolutions are somewhat flattened out and the consistency of the brain is firm The basal vessels are delicate At the base of both temporal lobes, but especially pronounced on the left side, there is an accumulation of opaque patches resembling somewhat tuberculous lesions The infundibular region and the pons are free from these changes

On frontal sections the gray matter is of normal width, pinkish bluish gray in color, with injected blood vessels It is very distinctly outlined The white matter is hyperemic but otherwise without gross changes The basal ganglia are well outlined and of the same appearance as the gray matter The ventricles are narrow The thalamus, subthalamus, floor of the fourth ventricle and gray nuclei of pons are highly hyperemic The gray matter of all these regions is distinctly pinkish in color

Spinal Cord The gray matter of the spinal cord is distinctly pinkish and because of this it is very well outlined There is considerable edema of the white matter of the spinal cord Its meninges are bright red and their vessels are injected

The histological findings in the meninges and the spinal cord were essentially the same as those of case 86 (Potter)

Medulla and Brain Stem The inflammation involved the medulla with unusual intensity The entire floor of the fourth ventricle was transformed into a large and continuous area of inflammation which rendered the differentiation of the single nuclei impossible The parenchyma was gravely affected and the tissue was flooded by countless neuronophagias, Hortega elements and astrocytes mingled with lymphocytes and leukocytes which migrated into the nervous tissue from the greatly irritated blood vessels (Figure 4)

The inferior olives remained essentially free, their parenchyma being well preserved The intensity of the disease subsided somewhat in the region of the lower corpora quadrigemina but the central gray substance contained numerous inflammatory foci

At the level of the nucleus of the nervus oculomotorius the inflammation was still very distinct in the nucleus of this nerve, but the substantia nigra and the red nuclei were but moderately involved

FIG 4 Anterior horn with scars Destruction of the parenchyma Multiple neuronophagia, pronounced glia response Lateral and posterior horns severely involved Microphotograph $\times 40$ Nissl stain

The inflammation could be continuously traced along the aqueduct and numerous foci were seen in the entire hypothalamic region and the thalamus. The pallidum, putamen, caudate nuclei, the white substance of the hemispheres and the cortex were free from pathological changes, but there was an outspoken acute meningitis at the base of the brain.

CASE AUTOPSY SUMMARY

Central Nervous System The histological picture in this case is characterized by a particularly severe affection of the medulla and brain stem including the hypothalamic region. The sympathetic nervous system is here involved practically throughout.

Thymus Persistent and hyperplastic, about one-third larger than normal for age and size. *Bronchial Glands* Small and black on sectioning. *Cervical Lymph Nodes* Not palpable. *Spleen* Measures 10 by $6\frac{1}{2}$ by $2\frac{1}{2}$ cm and weighs 100 grams. It is purplish red in color. The cut section shows marked congestion and hyperplasia of the lymphoid follicles. Marked passive congestion. Moderate lymphoid hyperplasia. *Large Intestine* Shows moderate congestion, few petechial hemorrhages and hyper-

plasia of the solitary lymph follicles *Small Intestine* Shows slight congestion and marked hyperplasia of Peyer's patches and solitary lymph follicles *Mesenteric Lymph Nodes* Hyperplastic Chronic hyperplastic lymphadenitis with stasis catarrh *Peribronchial Lymph Nodes* Hyperplastic, congested, with slight anthracosis *Adrenals* Hyperplasia of both cortex and medulla *Retroperitoneal Lymph Nodes* Hyperplastic lymphadenitis (C V Weller)

Pathological Diagnosis Acute meningo-encephalo-poliomyelitis of bulbar type Marked congestion, edema and small hemorrhages in brain substance Terminal hemorrhagic purulent lobular pneumonia Pulmonary congestion, edema and emphysema Subepicardial fatty infiltration Right-sided cardiac dilatation with relative tricuspid and pulmonary insufficiency Thymico-lymphatic constitution (hyperplastic thymus, generalized lymphoid hyperplasia, hypoplasia of aorta and adrenals) Passive congestion and parenchymatous degeneration of all organs

Case 100 Letha S, poliomyelitis, acute Entered the Hospital on the nineteenth day of the disease The history reveals the presence of the dromedary phenomenon The clinical record shows as leading manifestations, slight fever, marked headaches, constipation, marked irritability, psychoneurotic reactions, marked retention of urine, neck and spine signs, loss of knee reflexes Spinal fluid showed 160 cells, globulin four plus, mastic 223311, gold 0012222100 Paralysis of both lower extremities, and bladder Died 44 days after the onset of the disease

AUTOPSY

Central Nervous System The leptomeninges are thin and smooth, their blood vessels somewhat injected

On frontal sections, the gray matter is of normal width and appearance, the white

FIG 5 Multiple foci of inflammation in the floor of the fourth ventricle Parenchyma of most of the nuclei almost completely destroyed Olives not affected Microphoto graph $\times 10$ Nissl stain

matter contains countless blood points The basal ganglia are well outlined and without gross changes

The pons is of normal appearance but the medulla shows a pronounced injection of its blood vessels There is a definite hemorrhagic tinge to the gray matter of the spinal cord and there are small hemorrhages especially pronounced in the thoracic region The injection of the anterior horns can be followed throughout the spinal cord and increases again in the lumbar region where there are distinct red foci in the anterior horns

The histological picture of this case differs in many respects from the findings in the two foregoing cases

In the spinal cord there were countless neuronophagias and severe destruction of

FIG 6 Massive inflammation of both anterior horns in the lumbar region Parenchyma completely destroyed Gray matter flooded with countless glia elements and lymphocytes Blood vessels surrounded by massive infiltrations Microphotograph $\times 10$ Nissl stain

the parenchyma The infiltrations of the blood vessel system were unusually massive and consisted mainly of lymphocytes mingled with countless plasma elements and polyblasts Even the finest capillaries were surrounded by these cells which produced histological pictures of unusual intensity The glia response was in keeping with this The inflammation was particularly severe in the lumbar portion of the cord and somewhat less pronounced in the thoracic and cervical regions (Figure 5)

The meninges were thickly infiltrated by lymphocytes

In the medulla and brain stem only certain regions were affected The respiratory area was damaged throughout but the affection was not symmetrical at all levels There were pronounced inflammatory changes in the nucleus nervi vagi and trigemini

The substantia nigra presented quite an unusual degree of change It was affected in the same way and with the same intensity as were the lumbar segments of the spinal cord, and was completely destroyed (Figure 6)

The other nuclei of this region, including the substantia grisea centralis, and the hypothalamic region were practically free of changes but there were numerous foci in the thalamus

In the cortex of both hemispheres, especially in the parietal and temporal lobes, numerous small areas of inflammation were encountered. Their histologic structure was identical with that of the spinal cord lesions

FIG 7 Massive inflammation of the substantia nigra. Tissue flooded with countless glia elements and lymphocytes. Perivascular spaces contain dense infiltrates (lymphocytes and plasma cells)

CASE AUTOPSY SUMMARY

Central Nervous System The distribution of the inflammatory lesions is somewhat atypical in this case. The peak of the inflammation is reached in the lumbar cord, again in the substantia nigra and again in the respiratory area. The hypothalamic region is essentially free as are many areas of the sympathetic system, but large areas of the cortex in both hemispheres are affected. The histologic deviation lies in the character of the infiltrating elements which consist largely of plasma elements indicating an intense inflammatory lesion of some duration.

Lymph Glands Cervicals—no increase in size. *Mesenteric Lymph Nodes* Not found. *Retroperitoneal Lymph Nodes* Not made out because of large amount of adipose tissue present. *Hemo-Lymph Nodes* Not found. *Spleen* Cut section reveals moderate congestion, and slight increase in the amount of lymphoid tissue. The stroma appears to be somewhat decreased in amount. Atrophy, slight lymphoid exhaustion. *Encapsulated tubercles* *Thymus* Fatty atrophy of a persistent hyperplastic thymus. Small petechial hemorrhages in thymic fat. *Appendix* Lymphoid hyperplasia of slight degree. Lumen dilated. *Mesenteric Retroperitoneal Lymph Nodes* Slight lymphoid hyperplasia with sinus catarrh.

Rectum Contains a small amount of fecal matter. The mucosa near the anal orifice shows three or four shallow ulcers. These are irregular in outline. The

borders are slightly thickened. The floor of these ulcers is smooth and red in color. They are all located within 6 or 8 cm. of the anal orifice. The rectal mucosa higher up is negative except for rather marked congestion. (C. V. Weller.)

Lungs. Pulmonary arteries show recent embolism with induced thrombosis. Emphysema and atelectasis are present. Small atheromatous areas exist in pulmonary artery. Old caseating encapsulated tubercles in the bronchial nodes. Fat stain shows no fat emboli.

Pathological Diagnosis. Acute polio-encephalo-myelitis. Subendocardial fatty degenerative infiltration. Circulatory failure. Parietal thrombosis of right auricular appendage with localized interstitial myocarditis. Pulmonary embolism and induced thrombosis. Subepicardial fatty infiltration. Ulcerative proctitis. Aortic atherosclerosis. Colloid goiter. Lipoidosis of adrenals. Thymico-lymphatic constitution (fatty atrophy of persistent hyperplastic thymus, hypoplasia of aorta and adrenals, slight generalized lymphoid hyperplasia). Old tubercles in bronchial nodes and spleen. Passive congestion, moderate atrophy and parenchymatous degeneration of all organs.

It will be of interest to include the findings of two chronic cases, thus showing the characteristics of permanent changes after the lapse of nine and 30 years, respectively, for the purpose of illustrating our discussion on therapy.

Case 1. A boy of nine years and nine months had contracted poliomyelitis at the age of 13 months.

At autopsy the left hemisphere was found to be smaller than the right. The left side of the medulla was atrophic and the cortex of the left hemisphere appeared to be very narrow. Histologic examination showed in the left hemisphere pronounced and widespread degeneration of the parenchyma, numerous areas being almost wiped out. There were no inflammatory changes or tissue response and the blood vessel system was normal. In the atrophic side of the medulla many gray nuclei were destroyed. There were no changes in the cervical part of the spinal cord, the only part of the cord available for study.

Case 2. An entirely different picture was seen in the brain of this case coming to necropsy 30 years after an acute attack of poliomyelitis of the spinal cord. There was a diffuse degeneration and reduction in number of the ganglia cells in the anterior horns where most of the elements were greatly reduced in size and number and deeply stained. The tigroid was still partially visible. Some of these elements were round in shape, others retained the pyramidal form. There were also numerous yellowish weakly stained cells hardly recognizable as parenchymatous elements. Holzer sections revealed considerable glia production in the gray matter. There were no inflammatory phenomena of any kind nor was there any glia response. Weigert preparations failed to show a definite tract degeneration. The medulla and pons were free of changes.

In the substantia nigra a peculiar focal change was seen. The pigmented parenchyma elements were partly destroyed and others were reduced to cell shadows laden with greenish pigment. There were numerous weakly stained greenish nuclear elements, probably also remains of parenchyma. Large astrocytes and proliferating glial nuclei were scattered everywhere. Accumulations of gitter cells were usually present in the perivascular spaces. Finally, there were scattered fragments of black or green pigment. Only a small part of the formation was affected.

Examination of the basal ganglia showed that numerous focal lesions the size of a pinhead and somewhat larger, in which the parenchyma was destroyed, were present in the thalamus. The gray matter of both parietal lobes also contained small foci. They were organized by glia fibers but otherwise there was

CLINICAL COMMENT

It would seem from a study of these carefully observed cases that immunotherapy given in the pre-paralytic stage of acute poliomyelitis must have played a considerable part in bringing about the results obtained. Reference to the spot map of the Michigan epidemic, kindly furnished us by Dr Slemmons, will give the reader an idea of its extent in our immediate neighborhood. Forty-six and one-half per cent of the entire epidemic was concentrated in this vicinity and was contiguous to Washtenaw County, of which Ann Arbor is the county seat. These counties are Wayne (Detroit, the principal city), Oakland, Livingston, Ingham, Jackson, Lenawee, and Monroe. In other words, this was the center of the epidemic.* It is significant that of a group of 80 systemic cases in this area, most of which were intensively treated with convalescent serum and blood transfusions, none is paralyzed today.

There is also some evidence favoring the use of immunotherapy in the early stages of paralysis. It would seem from the progressive nature of the disease that this practice should be encouraged. It was a common observation to see the paralysis extending over a period of days and there are many reports in the literature in confirmation of this characteristic of the disease. Relapses of the disease are well known. One of our autopsied cases demonstrates this unusually well (case 100, page 536). We had regarded this patient as having fully recovered from the acute stage of the disease. It will be recalled that she did not enter our service until the nineteenth day of the illness. She died on the convalescent orthopedic service on the forty-fourth day of the disease. Autopsy disclosed a pulmonary embolus and induced thrombosis, which was thought to be the cause of death. Microscopic examination of the brain showed extensive acute inflammation in the respiratory center, sufficient to cause death.

Because of the widely disseminated vascular involvement which is invariably present, it would seem that this disease peculiarly lends itself to treatment directed at the vascular system either by direct intravenous and arterial measures or indirect intramuscular measures. Everywhere in the meningeal involvement the primary change and almost the entire change is vascular, indicating a breakdown of the meningo-vascular barrier. It would seem that intraspinal treatment might easily produce severe damage to the already widely affected parenchyma. The situation is entirely different from that found in a pure meningitis. The purpose of the therapy should be twofold. First, to neutralize the "toxins" by convalescent serum and blood transfusions, thus protecting the parenchyma from further damage. Second, to relieve edema, thus freeing the nervous tissue from excessive inflammatory response.

We are familiar with the fact that these same pathologic changes may result from infection that does not spread via the vascular system. That

* Number of cases per square mile greater

is, infection or exciting cause may travel along a nerve trunk, and there is still other evidence which we will present in a subsequent paper, that infection does not necessarily travel via the blood vessels. However, no matter how the infection travels its result is always perivascular infiltration and glia hyperplasia. With this fact in mind it still seems logical to expect that anti-infectious agents must reach these diseased areas via the blood stream.

Physiologists agree that the cerebrospinal fluid is manufactured by the choroid plexuses and passes into the subarachnoid space from the ventricular system. A small amount of the cerebrospinal fluid is delivered to the subarachnoid space via the perivascular spaces that empty into it. In other words, the flow in the perivascular spaces is toward the subarachnoid space. The pressure in the subarachnoid space is greater than the venous pressure. The fluid is absorbed by the subarachnoid villi into the venous sinuses³⁸. Substances injected into the spinal canal may be recovered from the veins of the neck in from 30 to 40 seconds, from the stomach and bladder in from 10 to 20 minutes.

Our experience leads us to recommend that 20 to 30 c c of convalescent serum in the vein, 20 to 50 c c in the muscle, and a transfusion of 100 to 200 c c of convalescent or adult whole blood be given, if possible, to all definitely diagnosed systemic cases and to those in the early days of the paralysis. As large doses as possible should be given. From information gleaned from the use of serum in the prevention of experimental poliomyelitis in monkeys a concentrated serum is indicated.

We are impressed with the great benefit that may accrue from the use of intravenous glucose, particularly in the bulbar cases, and also at times in the systemic and spinal paralytic stages. Theoretically, it should be beneficial in the pre-paralytic stage because much damage comes from edema, and because of its effect in improving volume blood flow. We have seen headache, pain, muscle tenderness and circulatory collapse relieved or caused to disappear by its use. Increasing the osmotic pressure of the blood by means of intravenous hypertonic solutions aspirates the cerebrospinal fluid from the shrinking brain tissue causing a reverse flow in the perivascular and ventricular systems³⁷.

We are confronted with the request for a satisfactory control for the results we have recorded—for a similarly diagnosed group not treated by immunotherapy. Under the existing circumstances as previously set forth this was impossible.

Perhaps the majority of those who have had much experience with the use of convalescent serum in the treatment of acute poliomyelitis in the pre-paralytic stage are favorably impressed with its action. The favorable literature is quite well known. A few references to it will suffice. Aycock²⁹ (1927), McEachern and Bell³⁰ (the Manitoba epidemic, 1928), Shaw, Thelander and Limper³¹ (the California epidemic, 1928), Aycock and Luther³² (a New England epidemic, 1929), Lomer and Shirreff³³ (the

Ottawa epidemic, 1929), a particularly convincing report, and the general review by Amos³⁴ in 1930

It would, however, seem particularly important to give heed to all constructively critical reports. We must give particular thought to the mature and exacting judgment of Dr Park and his associates. Dr Park³⁵ remarks, after a careful analysis of a large series of cases: "The results of observations on treated and untreated patients in the pre-paralytic stage of poliomyelitis during the 1931 outbreak (New York) do not give any statistical proof that the serum has any value when given in cases after the cells of the central nervous system are involved. By this involvement we mean the exhibition of the various manifestations of the sympathetic nervous system and the changes in the spinal fluid." Dr E L Godfrey³⁶ of the New York State Department of Health, discussing Dr Aycock's paper, questioned the validity of his findings because of the lack of a satisfactory control. We wish to point out the difference in the methods we used in the treatment of our cases, i e, the addition of blood transfusions.

It may be that the question turns on the pivots of earliness of diagnosis, thoroughness of the education of physicians and public, and the strenuousness of propaganda. The management of the Ottawa epidemic offers one of the best examples of this practice. Without a parallel control and even without a large preeducation campaign series of cases for comparison, one is quite easily convinced of the favorable influence of convalescent serum in that epidemic. The same is true of the Manitoba epidemic. Here a parallel control is recorded. Blood transfusions were not given in these series.

It may be that in a community like Ottawa, information of this nature would be more likely to become the possession of the entire public, to be more widely disseminated and better understood than it would be in a very much larger community made up of a greater number of types and nationalities. If we compare the cases in our small community with those of the much larger community represented by 860 cases selected from the State at large by the Michigan Commission, suggestive figures are obtained. Of the latter, 45.1 per cent became paralyzed, 47.7 per cent were not paralyzed. In our series only 3 per cent were paralyzed and all completely recovered. In his final paragraph, Dr Park remarks, "Nevertheless, the uniformly optimistic opinions of those who have not observed untreated patients for a comparison cannot be entirely disregarded." We have recorded these cases with the hope that similarly treated series of cases will be reported, particularly with adequate controls, and that our results may be helpful in the final solution of the question as to whether immunotherapy is of value in the treatment of acute epidemic poliomyelitis. We have called attention to the possible relation of blood group to the severity of the disease. Our cases are too few in number to be more than suggestive.

PATHOLOGICAL COMMENT

We designate the disease process which is characterized by a mesodermal response in conjunction with certain transformations of the neuroglia as encephalitis. This histological symptom complex in encephalitis is a defense reaction in the sense of Aschoff. The histologic criteria in acute poliomyelitis correspond to the following formulations. The mesoderm, that is, the blood vessels of the central nervous system, responds by a production of lymphocytes, polyblasts and plasma cells, and leukocytes are attracted from the blood stream. The glia produces Hortega elements and astrocytes as well as glial nodes. All this is directed against a living virus. *We are therefore dealing with an acute encephalitis.*

The histological picture varies considerably according to the duration of the disease and its acuteness. In stormy cases of short duration considerable numbers of leukocytes may be present. This was noted in case 86. In the majority of the cases however, it is known that the leukocytes disappear within a few days but that occasionally they may dominate the histologic picture. Luksche¹ described a case of acute poliomyelitis with typical distribution of the disease, in which the infiltrating elements were predominantly leukocytes. In the anterior horn the leukocytes formed themselves in dense masses in the gray matter and occupied the perivascular spaces. Hauptli² confirmed the presence of leukocytes in the perivascular spaces as well as in the gray tissue by the oxidase reaction. The same results have been obtained by Wohrmann³. According to Hauptli, the leukocytes are present during the first six days of the disease. This is also in accord with our findings.

The lymphocytes appear at the same time as the leukocytes. They are present during the entire period of acute inflammation. The perivascular infiltrations consist mostly of these cells and they frequently migrate into the gray substance.

The plasma elements for the greater part do not appear in the acute stages. They are more characteristically found in later stages of the disease. They were present in case 100, which terminated fatally 44 days after the onset. They are confined to the perivascular spaces and do not enter the nervous tissue.

The response of the glia and the destruction of the parenchyma is a very impressive finding. A very common type of glia reaction is represented by neuronophagia which is a *phagocytosis* of the *dying ganglia cells* by the proliferating microglia. According to Creutzfeld⁴ and others, this neuronophagia is purely a glial response. That is, leukocytes or polyblasts never appear in these foci, never engage in the process of neuronophagia, and the oxidase reaction is therefore always negative.

The neuronophagia, which is almost always present, indicates heavy destruction of the parenchyma. The parenchyma in poliomyelitis is destroyed within a few days. This is an important fact from the standpoint of therapeutic consideration.

Frequent as the neuronophagia may be, it is not uniformly present. It may be missing even in the most acute stages of the disease. In the observation of Wohrmann³ neuronophagia was absent in spite of marked parenchyma destruction and acute glia response. Sharp and Nelson⁵ had a similar experience.

In very rare instances the glial reaction may be entirely absent, as has been reported by Thomas and Lhermitte⁶. In this case, not even Hortega elements were formed although the ganglia cells were destroyed and the connective tissue response was typical.

The destruction of the parenchyma has naturally attracted great attention and some authors have gone so far as to regard the parenchyma degeneration as independent and preceding the inflammatory phenomena. Recently Hurst⁷ again advanced this view, but it cannot be accepted. As mentioned above, poliomyelitis is an acute inflammation of the nervous system and such a condition is never brought about by ganglia cell destruction. Ganglia cell destruction is the result of an inflammation but not its cause. The alteration of the parenchyma constitutes only a part of the inflammation, the ganglia cells suffer in the same way as do the parenchyma elements of other organs under similar conditions.

In certain cases repeated attacks of acute poliomyelitis have been seen, thus we observed in case 100, in which there was a relapse before the end of the first attack. Still⁸ has reported relapses at intervals of from eight days to 12 weeks. Obviously there occurs in such cases a breakdown of immunity which in poliomyelitis is not always acquired and which is not always a permanent factor. Still describes the case of a child who contracted poliomyelitis at the age of 21 months and suffered a permanent paralysis of the left leg. The second attack at the age of 7½ years left no damage.

Peremans⁹ reports the case of a child of four years and nine months, with a second attack three months and a third attack two years after the first one. The child survived. The second attack may be fatal no matter when it occurs, whether a few weeks after the first onset as in our observation (100) or several years later, as in the case of Marinesco and Draganesco¹⁰. In the latter instance, acute changes of the second attack as well as old scars and parenchyma degeneration of the first were present.

As has been pointed out, the virus of this disease affects the anterior and posterior as well as the lateral columns of the spinal cord, the gray masses of the medulla and pons, of the subthalamie region, and of the wall of the third ventricle. All of these regions contain numerous centers which are a part of the sympathetic nervous system. *Acute poliomyelitis is to a great extent a disease of the sympathetic system.* In the clinical picture even in the acute stages, it will be noted that there are many symptoms which confirm this view, one of the most important features being the disturbance of the respiratory area. The frequency of this type of disturbance is in accord with the frequency of anatomical lesions in this region which was affected in all of our autopsied cases.

According to L  chelle, Baruk and Douady¹¹ vasomotor and sympathetic disturbances may result from the involvement of the lateral horns characterized by pains of radicular type and vasomotor and sympathetic disturbances in the extremities

The frequency of the affection of the sympathetic system has been shown by Wernstedt¹² who examined 6775 cases of the great Swedish epidemic of 1911-1913. He reported numerous instances of accommodation, bladder and anal sphincter palsies, as well as those of the lips, tongue and vocal cords

In other instances the involvement of the sympathetic nervous system is restricted to certain brain stem nuclei. A great deal of attention has been paid to isolated facial palsies frequently occurring in epidemics of poliomyelitis, a number of which were observed in this series. Radovici¹³ saw 15 cases and Stern¹⁴ had a similar experience. The isolated affections of the abducens (sixth) and motor oculi (third) nuclei (case 95) (Lundsgaard¹⁵) as well as those of the vagus (Nemlicher¹⁶) also belong here. Disturbances of the bladder in the initial stages of the disease have been reported by Bugbee,¹⁷ and observed by us in two cases. All of these localized types of poliomyelitis were acute in character and were frequently fatal. None of our facial cases were fatal. One of our bladder cases died.

In a few instances the affection of the sympathetic nervous system has run a chronic course. Mendel¹⁸ described a peculiar, slowly increasing, bluish discoloration of the left leg in a young male. This extremity became cool and gradually an atrophy of thigh and calf, including the bones, developed. Hyp  sthesia, hyp  lgesia and hypothermia were noted. According to Mendel the clinical picture was caused by the involvement of the lateral horns of the spinal cord. Chronic progressive palsies of arms and legs associated with severe muscle atrophies have been seen by Comfort¹⁹. Particularly severe and remarkable were the disturbances in the observations of Sterling²⁰ and Foster Kennedy²¹. Sterling described palsies of the legs, of the muscles of the trunk and of the left facial nerve, acute bilateral panophthalmia and slowly progressing atrophy of the face involving its skin, muscles, bones and teeth. The author interprets his findings as a vegetative trophoneurosis. Foster Kennedy saw in a boy of 12 a sudden complete paralysis associated with a loss of bladder and rectal control. In the third week of the disease, lanugo hairs appeared all over the body. The patient recovered but the hair of the head stopped growing for several months.

The pathology of these chronic affections of the sympathetic system is but little known. Two possibilities have to be considered: (1) destruction of certain gray nuclei, and (2) changes in the paravertebral sympathetic trunks, or both.

Histologic changes in the sympathetic ganglia of the trunk and even in those of the intestines have been reported several times, but they are not convincing. Chronic lesions of the brain have been described in the litera-

ture in rare instances. Gross involvement of the brain has been described by Koenig,²² who reported hemiatrophy of the body and the extremities, which in some instances but not in all was associated with hemiatrophy of one of the hemispheres. We are able to confirm this finding. (See page 539.) The degeneration of the sympathetic nuclei in the medulla has been demonstrated by us in one chronic case. Bouttier and van Bogaert²³ reported diffuse degeneration of the spinal cord including the lateral horns, a finding similar to that described in the cord of our second chronic case.

The number of observations of chronic cases is, however, too small to warrant conclusions, but we have reason to believe that chronic changes of the sympathetic nervous system are more frequent than is generally known. This suggests the importance of investigating the possibility of preventing further development of the disease after the first signs of paralysis have developed. Our observations show that the poliomyelitis may very well produce severe and permanent destruction of the gray matter and that the disease is not always restricted to the spinal cord and the brain stem. The earlier in life the infection takes place the more damage it can do. In an infant with undeveloped and delicate nervous system the disease may interfere with further mental progress and produce idiocy or feeble-mindedness. The course of the disease in an infant is much more severe than it is in an older child.

Clinical, histological and etiological considerations have been used in order to work out a pathologico-anatomical classification. It has proved to be impossible to harmonize them. The etiology of poliomyelitis is not known and the histologic findings are shared by other types of encephalitis. These were the reasons which compelled H. Spatz²⁴ to propose a new classification based on the modus of the distribution.

Acute poliomyelitis is characterized by the involvement of the gray tissue of the spinal cord and brain stem. It is, therefore, a polioencephalitis and treatment must be directed at wide and scattered areas of infection. The distribution of the inflammation in the affected areas is spotty. This peculiar modus of distribution as well as the histologic response is shared by rabies, epidemic encephalitis, and the so-called Borna disease in horses. They constitute, therefore, one histologic group.

The similarity is limited to the acute forms of these diseases. The chronic conditions present entirely different pictures. Poliomyelitis destroys numerous gray nuclei in the spinal cord, in the medulla, the brain stem, and in wide areas of the gray matter—lesions which are very unusual in epidemic encephalitis. In the latter only the substantia nigra suffers a permanent degeneration and the resulting histologic picture differs fundamentally from that which we observed in the same region in our second chronic case. Chronic rabies is not known. The four diseases in question are four independent biological units produced by different, although in all instances ultramicroscopic viruses. Their therapy and their prophylaxis may be found to involve the same principles.

Different views have been advanced for the explanation of the peculiar distribution of the disease in the central nervous system. Spatz is of the opinion that the virus may reach the brain by way of the spinal fluid because the basal parts of the brain and its inner surfaces, as for example the walls of the third and the floor of the fourth ventricle, which are exposed to the spinal fluid, are particularly affected. He thinks that the virus travels through the peripheral nerves and reaches the spinal fluid in this way. This view may seem to be confirmed by experimental transmission of the virus through the ischiatic nerve or the cervical ganglia (Marinesco,²⁵ Hurst²⁶). Such an assumption, we think, is not tenable because typical infection may be produced by intracerebral injection without involving the spinal fluid.

Jungeblut and Spring²⁷ separated the lower part of the spinal cord in monkeys and closed the dura so that the spinal fluid passage remained free. An intracerebral inoculation produced a typical poliomyelitis in the animal but the infection did not pass the lesion. The virus traveled, therefore, through the nervous tissue itself, and not by way of the spinal fluid. This may lend further support to our feeling that intraspinal serum is unnecessary.

The pathology of the body organs in poliomyelitis is unimportant. The changes in the lymph glands as described by Flexner, Peabody and Draper,²⁸ 20 years ago, and by us, are characteristic of status thymico-lymphaticus. They are not peculiar to poliomyelitis. Catarrhal inflammation of the intestinal mucosa and of the lymphoid structures is not uncommon in other infectious diseases in childhood. It seems to us that the somewhat revolutionary view of Burrows, who believes that poliomyelitis infects first the lymphatic structures and only secondarily and in rare instances the nervous system, is rather speculative. Cowie and Lowenberg* have noted these general lymphoid changes in experimental poliomyelitis in monkeys inoculated intracerebrally.

From the standpoint of symptomatology, there is abundant evidence of central nervous system involvement in a very large percentage, if not in all, of the cases which do not go on to the stage of paralysis. There seems to be evidence of a systemic stage of this disease prior to involvement of the nervous system, as there also is in epidemic meningitis. This favors the opinion that the virus is probably carried to the central nervous system by way of the blood stream and encourages therapeutic effort via this route, although it is well known that the virus may travel along the nerve sheath, as has been accomplished experimentally. Dr. Flexner's well known experiments on monkeys show that the disease virus may travel through the nose directly along the olfactory nerves, and there is rather convincing evidence that the virus enters the body through the nasal passages in man. We have not been able to demonstrate changes in the olfactory

* Unpublished records

nerves We have seen involvement of the cranial nerves after intracerebral injection of poliomyelitis virus in monkeys

SUMMARY

In the four cases of acute poliomyelitis that came to autopsy, there was an acute inflammation in the spinal cord and brain stem in all and in the gray matter of the brain in one In one case the spinal cord alone was available for study

In the spinal cord, anterior, posterior, and lateral horns were affected and the greater part of their parenchyma was destroyed Neuronophagia was very frequent and the glia response was very active The blood vessel system of the cord was severely involved

In the medulla and brain stem numerous gray nuclei were affected in the same way as the gray matter of the spinal cord, the floor of the fourth ventricle being particularly involved There were numerous foci in the thalamus in two cases In these the inflammation was spotty, the foci being not always interconnected The gross pathology invariably showed extensive edema The progressive nature of the involvement was very apparent

Two chronic cases were also examined In one, there were numerous old degenerative foci in the gray matter of the spinal cord, in the substantia nigra, in the thalamus and in the gray matter of the brain In the other, large areas of the gray matter were destroyed and the medulla was hemiatrophic

The histologic picture varies in relation to the duration of the disease, it is dominated by the destruction of the parenchyma

Acute poliomyelitis shows a far-reaching conformity with acute epidemic encephalitis, rabies and Borna's disease of the horse Poliomyelitis affects the sympathetic system to a great extent It may cause idiocy if it occurs in infancy

CONCLUSIONS

1 We have recorded a study of 125 cases of epidemic poliomyelitis including data upon which our conclusions are based, 81 in the pre-paralytic stage, 44 in the paralytic stage The cases developed in the center of the epidemic There are also recorded a few chronic cases for purpose of discussion

2 Eighty of the pre-paralytic cases were under our complete control They received either convalescent serum, convalescent or adult whole blood transfusion, or a combination of these by the various routes of administration Seventy-seven, or 96 per cent, of these did not develop paralysis In those developing paralysis, recovery was complete No case shows any residual paralysis today

3 Twenty-seven of the paralyzed cases received immunotherapy as soon as they came under observation Of these 33½ per cent showed

definite improvement Three completely recovered, five died Seventeen paralyzed cases received no immunotherapy, 11.6 per cent improved, 86.64 per cent showed marked residual paralysis with little or no recovery

4 The progressive nature of the pathologic involvement of the central nervous system as observed clinically strongly suggests that immunotherapy and osmo-therapy should also be carried on in the early stages of the paralysis

5 Acute poliomyelitis involves the gray matter of the spinal cord, the nuclei of the brain stem, and the walls of the third ventricle It is, therefore, mainly an infection of the sympathetic nervous system The basal ganglia and the cortex are in some instances involved Scattered foci may be present in the white matter

6 Histologically the disease is characterized by the involvement of the neurons which are destroyed by the so-called process of neuronophagia

7 The inflammatory edema which is present in all acute cases must be regarded as an important factor in therapy and must be relieved

8 Epidemic poliomyelitis is a non-purulent type of inflammation It is one of a biologic group of diseases comprising rabies, epidemic encephalitis, and Borna's disease of horses

9 Histologic examination of chronic cases shows that in some instances the infection involves the entire cortex and interferes with the further development of the nervous system, producing feeble-mindedness and idiocy

10 The importance of the involvement of some of the brain areas, for example, the substantia nigra, is not manifested clinically as is a similar involvement following epidemic encephalitis by the Parkinsonian syndrome

11 Clinico-pathologic data are given which should assist in determining the results of the therapeutic measures employed

12 Blood group may be an influencing factor in the severity of the disease Seventy-seven per cent of the pre-paralytic cases fell in Types IV and III, 58 per cent of the paralyzed cases fell in Types II and I

We wish to express our sincere appreciation of the devoted assistance during the epidemic of Dr Dorman E Lichty and Mr William Hicks of the Contagious Hospital Staff, Miss G Kleinheksel, supervising nurse, and Drs Norman Capener and Louis Yglesias of the Orthopaedic Staff

VIRUS DISEASES OF ANIMALS TRANSMISSIBLE TO MAN*

By K F MEYER, *San Francisco, California*

INFECTIONS or diseases of animals associated with or due to incitants generally designated as viruses, since 1892, have attracted more and more attention. In fact, these maladies, single or in epidemic distribution, have assumed an important position in the realm of the heterogeneous infection chains.

The insect-borne diseases, yellow fever, dengue, pappataci fever, Rift Valley fever, etc., are caused by filterable incitants, which localize and multiply in the poikilothermic hosts and, consequently, are classed with the heterogeneous infections. Between the causative agent of the disease and the poikilothermic host, a specific mutual relationship exists and the insect (mosquito) is not merely a vector or transmitter but a definite host. A well regulated cyclic organization continuously shifts the relative position of man and insect. As far as the available information indicates, the disease incitant is never transmitted from man to man nor is it spread from insect to insect. Doubtless the continuous change between vastly different hosts must be accompanied by alterations in the biologic activities of the virus of the disease concerning which very little is known. Of interest is the further observation that the vector is slightly, if at all, affected by the virus. For the preservation of the parasite, this behavior is of the greatest importance. Should the vector succumb to the disease incitant or should the desire to suck blood disappear, then the transmission to man would cease and the chain would be regularly broken in the insect. In due course, the disease would become rarer and finally disappear entirely.

There is a second and decidedly larger group of infectious diseases, which may be conveyed from warm blooded animals either by the percutaneous, the alimentary or the permucosal routes to man. This group comprises virus infections, which are quite variable with respect to their localization, portal of entry and mode of transmission. Some of the incitants responsible for the diseases of this group possess a broad pathogenicity range, they are capable of infecting, in nature and experimentally, a great many hosts. Thus in nature, rabies is confined to a comparatively small number of species, dogs, cats, coyotes, foxes, wolves, jackals, horses, cattle, pigs, deer and moose, but artificial transmission is possible among a wide range of animals. In fact it may be assumed that no mammal or even bird is insusceptible. As a rule, the infection chains are broken following the first transmission to man. The restricted mode of natural transmission—percutaneous introduction of the virus through a bite wound as in rabies

* Read at the Chicago meeting of the American College of Physicians, April 16, 1934
From the George Williams Hooper Foundation, University of California, San Francisco, California

—is in part responsible for this behavior. A change of host, as for example a transfer to man, will sooner or later lead to a blind ending of the chain. A continuous passage in the animal host is obviously an absolute necessity. In some of the infections in man the clinical and anatomical characteristics are identical with those of the disease in animals. The neurotropism of the rabies and louping-ill virus is fully preserved. On the other hand, pulmonary manifestations are rarely seen in psittacine birds suffering from psittacosis, while they are the prominent symptom in the clinically recognized human infections with this particular virus.

Although it is the purpose of this paper to outline the effects of certain viruses, it may be permissible to inquire quite briefly into their nature. By usage, the term filterable virus is applied to a noxious agent or poison susceptible of being passed through a diatomaceous earth or kaolin filter impervious to ordinary bacteria. To a certain extent, this term is misleading since bacteria and spirochetes have been found capable of penetrating such filters, and a few incitants and the diseases caused by them have been placed with the filterable viruses even though they have not been shown to be filterable or only pass the filters with difficulty (rabies). The numerous painstaking studies of recent years have shown that many of the viruses are not merely enzymes or transmissible mutagens as was originally intimated by Beijerinck's description of the tobacco mosaic disease as a *contagium vivum fluidum*. In fact the evidence secured by special staining procedures (Borrel, Paschen, Goodpasture and Woodruff, Cowdry and others), dark field-ultraviolet microphotography (Barnard), differential centrifugalization (Bechhold and Schlesinger, Eagles and Ledingham, Bedson), ultrafiltration (Bechhold, Krueger, Elford), immunity reactions (Smith, Ledingham, Andrewes) and photodynamic inactivation (Perdrau and others) indicates that the viruses are, in all probability, living infectious, biologically defined particles capable of reproducing themselves true to type. Their sizes vary from 10 to 170 $\mu\mu$. They are obligate cellular parasites but thus far no one has succeeded in growing them on lifeless media. Since they cannot regenerate in the absence of living cells, their existence is demonstrated by their activity in susceptible hosts. However, the immunity reactions, which are employed, reveal a remarkable relationship between bacteria and viruses. Antigenically different types of viruses may incite identical symptoms (several viruses are capable of producing encephalomyelitis). Further, the corpuscular infectious particles are specifically agglutinated by antisera (vacinia) or the heated precipitable virus substance behaves like a hapten and incites skin reactions in the vaccinated human beings. In time these observations may be of aid in the preventive and curative aspects of the diseases caused by viruses but for the present the existence of such an agent is demonstrated by its activity in the natural and experimental host, in filtrates of tissues and in tissue cultures. The transmissible agents, in all probability animate in nature, are, therefore, judged by their activities and not by their morphologic or biochemical behavior.

Turning now to a consideration of the animal diseases caused by viruses transmissible to man, it may be profitable to confine the review to certain recent observations on rabies, Rift Valley fever and louping-ill, then to consider the problems regarding the possible transfer of foot and mouth disease, distemper and equine pernicious anemia to man and finally to discuss the psittacosis problem in the light of unpublished data collected in California

RABIES

Although not a disease of any great consequence in the total mortality of animals and man, the fear inspiring character of the symptoms and its mode of transmission, so vividly described by Fracastorius (1546), continue to hold the imagination of the investigators. The study of the causative agent, the aberrant types of the viruses and the modifications of the Pasteurian treatment remain fascinating problems.

In the fall of 1931, I received from Professor Rosenbusch of Buenos Aires a sample of a glycerinated brain specimen of a rabbit, which had been injected with nerve tissues of a cow dead from "Mal de Caderas." According to the accompanying letter, a comparative test with the rabies virus was suggested. The specimen was inoculated into rabbits and found to behave like a rabies virus, typical Negri bodies were readily demonstrated in the hippocampus. Shortly afterwards, a communication was received from Dr J L Pawan of Trinidad, who desired reprints and information concerning botulism in cattle. From a reprint of an article by Hurst and Pawan which was enclosed, it was noted that an epidemic affecting man and beast had appeared in Trinidad, and although the veterinary experts had diagnosed the disease in cattle as botulism, the evidence strongly pointed in the direction of a specific encephalomyelitis. Thus, an analysis of the relationship between the South American cattle and horse disease and the epidemic in Trinidad appeared desirable. Quite briefly, the facts established to date are as follows:

Since 1914, no case of rabies has been recognized in Trinidad, an island on which the strictest quarantine laws against rabies are in force. However, in 1929, cases among the human population simulating acute poliomyelitis made their appearance. Mainly children of school age were affected, and the 20 cases, which occurred in 1931, all ended fatally. The symptoms were those of paresis of the limbs, bowels and bladder, loss of sensation in the limbs and abdomen. A fatal termination ensued after an average of 8.5 days. The paresis followed an ascending course. Portions of brains sent to the Lister Institute, London, and to the Rockefeller Institute at New York produced on monkeys a virus infection indistinguishable from rabies. Negri bodies "Innen Korperchen" were regularly demonstrated. In the dog, the manifestations of paralysis predominate, those of biting are absent. Cross-immunity tests showed that the fixed virus protected in a certain number of cases against the intracerebral inoculation of the Trinidad virus, while immunization with the Trinidad virus protected

to a much lesser degree against the fixed virus. Results of serum neutralization tests showed evidence of a similar cross-immunity. Neuropathological lesions agree well with those recorded in cases of paralytic rabies. The anterior and posterior horns are equally affected, thus differing from the picture in poliomyelitis.

The features of the cattle disease were salivation, paresis of the legs, and a fatal termination after five or six days. A brain was sent to Hurst, who reported the presence of the rabies virus. The diagnosis of botulism had been based upon the clinical features of the cases, and upon the detection of the spores in the soil from the farms where cases had occurred. In two cows, the *Clostridium* was recovered from the liver and the spleen.

The epidemiological features of the human and cattle disease, both of which may be accepted as a form of rabies, are of greatest interest. In this connection, mention must be made of the reports by Haupt and Rehaag, who studied a cattle disease in Brazil as early as 1921, and of those of Costa and A. Costa and Rosenbusch in Argentina, and Migone in Paraguay during 1930 to 1933. These authors all agree that the disease is not contagious, has an incubation time of as long as two and one-half months, and is caused by the virus of rabies. Remlinger and Bailly, who tested the same virus as was sent to me, have definitely pronounced the Paraguayan virus to be a true rabies. On the other hand, Kraus and Duran, who experimented with the Trinidad and the South American virus, consider both to be varieties of the true rabies virus and designate it as *Paralyssa*.

Haupt and Rehaag were the first to establish the fact that the cattle had been bitten by vampire bats. In fact, the laboratory experiment of a bat biting a cow confirmed the supposition that these creatures were the vectors. In Trinidad, Dr. Pawan has demonstrated Negri bodies in the brain of a bat with unusual behavior. The occurrence of the cattle epidemics in the vicinity of wooded areas spoke in favor of a flying forest animal, the *vampire bat*—*Desmodus rufus*—and not the dog. A heifer, bitten 27 days before, died with symptoms of dumb rabies. The only human case at Trinidad, in which there was a history of a bite, occurred on July 6, 1931, and that was the bite of a bat. Symptoms developed on August 3, i.e. after 28 days. According to a more recent report, in three of the human cases mentioned by Hurst and Pawan, there was a definite history of a bite by a bat. Since this is not an uncommon occurrence in Trinidad, the investigators are of the opinion that final proof is lacking, although the evidence strongly incriminates the vampire bat as the transmitter of the disease. How the infection is spread among these mammals, and how they ever came in contact with a rabies virus remains a fascinating problem to be solved.

That rabies may show no tendency to spread among dogs is clearly shown by the observations made by du Toit in South Africa, who found that the yellow mongoose (*Cynictus pennicillata*) and the genet (*Genetta felina*), two wild carnivora, have caused human infections. The presence of rabies has been confirmed by an examination of the brain of a sick mon-

goose caught in the veldt How difficult the control of rabies may become, when the eradication of the transmitter is practically impossible, is well illustrated by these observations

The statistical reviews on antirabic treatment continue to emphasize the relatively low proportion of neuromuscular accidents following the use of dried or glycerinated cords However, the incidence is still much greater than after treatment by killed carbolyzed vaccines The subject of antirabic inoculation of dogs and domesticated animals with chloroform or phenol treated vaccines, or those fixed by passage from dog to dog has not crystallized into a unanimous verdict Although declared safe and efficient, the methods can serve only as an aid in the control of an outbreak of rabies In the United States, the elimination of the stray dog remains the major problem

RIFT VALLEY FEVER OR ENZOOTIC HEPATITIS

In 1931, Daubney, Hudson and Garnham described a virus disease affecting sheep, cattle and goats in the Rift Valley of the Kenya Colony Very young lambs are highly susceptible, and a mortality of over 95 per cent has been observed In ewes and cattle, the losses are relatively low Anatomically, characteristic lesions, in the form of a focal necrosis resembling that of yellow fever, are regularly encountered Infection through contact has not been observed, although the blood of the diseased animal readily conveys the malady by inoculation Preliminary experiments and field observations suggest an insect, probably *Taeniorhynchus brevipalpis* as the vector By moving the flocks of sheep from the mosquito belt to higher altitudes, the abortions and mortality in the ewes and lambs may be checked

Not the least important point connected with Rift Valley fever is the fact that the virus is pathogenic for man Four of the investigators who made the postmortems on the experimentally infected animals became infected In every case the attack was characterized by a very brief period of general malaise, the temperature rose to about 103° F, persisted for 12 to 36 hours, and was followed by headache and pains in or near the joints Every native engaged in the herding of sheep during the epidemic became ill for a period of four days In fact, close to 200 human cases of Rift Valley disease without any fatality are known to have occurred To prove the nature of the infection and to study its effect on a malarial infection, a man was injected with the diluted filtered virus On the third day, he developed a febrile reaction and felt ill Blood taken daily from the patient, infected lambs for a period of five days Clinically, Rift Valley fever in man resembles sand fly three-day fever It is differentiated from dengue fever by the fact that no rash, enlarged lymph-nodes or saddleback temperature chart accompanies the Rift Valley fever Subclinical infections have been recognized with the aid of the complement fixation test Incomplete evidence suggests the possibility that certain African rodents might serve as reservoirs

LOUPING-ILL

For more than a century, a disease of sheep on farms in certain areas of Scotland has been discussed and attempts have been made to determine its etiology. Early in 1929, Pool, Brownlee and Wilson succeeded in experimentally reproducing the condition in sheep and pigs by inoculations of portions of the central nervous system from diseased animals. The infective agent, which is filterable, was also found occasionally in the blood.

Subsequently, it was shown by Gordon, Brownlee, Wilson and McLeod that the ticks (*Ixodes ricinus*), which transmit the virus, also harbor another infective agent which causes a febrile disease in sheep. However, the most important discovery was made by Alston and Gibson, who transmitted the virus to mice by intracerebral injections. Thus a means was made practicable for a more extended use of this virus for laboratory studies.

In this connection it is worth remembering that the investigators emphasized the high infectivity of the virus. Contact of uninoculated with infected mice resulted in cage transmissions. This infectiousness has now resulted in laboratory transmission to man. Rivers has recently studied such cases by neutralization tests and has shown that persons who have had intimate contact with the louping-ill virus either develop a definite encephalitis, an influenza-like disease, or pass through a cryptic infection. The literature reports no spontaneous cases of louping-ill among men in the regions in which the disease is common in sheep. These laboratory observations will doubtless lead to further inquiries.

FOOT AND MOUTH DISEASE

The transmission of the virus to man must be considered as established, but its occurrence is quite rare. Despite numerous reports in the literature, undoubted cases characterized by an abrupt onset with fever, followed shortly by a vesicular eruption on the lips and mouth, the palms, soles and about the nails, and prompt recovery within two to four days, are few. Since a differential diagnosis cannot be made on clinical grounds, the reports of many exanthemata diagnosed as foot and mouth disease, without an infection or cross-immunity tests, are of little value. The susceptibility of man must be remarkably low, or otherwise it would be impossible to explain the absence of human infections following the use of small-pox vaccine contaminated with the foot and mouth disease virus. Thorshaug and Magnusson from Norway, and Motas from Rumania report such observations. The vaccine contained the foot and mouth disease virus in a highly virulent form and, when transferred to cattle and hogs, induced fatal infections. Equally convincing are the reports that only two proved human infections originated in the Institutes specially devoted to a study of the disease. To date, the number of human cases of foot and mouth disease, proved by transfer of the bleb content to susceptible animals, is, according to Trautwein, three (Pancera, Gerlach and Trautwein). The illness of a 25

year old caretaker, who accidentally cut his index finger on the right hand while infecting cattle with the foot and mouth disease virus, is particularly instructive. Two days after the accident, a small, burning bleb developed at the site of the already healed wound. Within two days, a multiple eruption appeared on both hands and feet. There was no rise in temperature nor general malaise. Within six days the blebs began to dry and about the sixteenth day after the onset, the crusts had fallen off. The contents of the blebs were tested on guinea pigs and a young pig. A type "B" foot and mouth disease virus was demonstrated. The blood of the convalescent contained neutralizing antibodies against the virus type "B," but not against type "A" or "C." Thus far, transmission from man to man has not been demonstrated, the infection chain is obviously broken.

INFECTIOUS ANEMIA OF HORSES

The transmissibility of the virus of infectious anemia of horses to man is of twofold interest. Although the only two human cases reported and proved refer to a German and a Dutch veterinarian, who both had intimate contact with diseased animals, it must be remembered that the virus may persist in the blood and tissues of horses for years and the affected animal may not appear anemic or sick. Since horses are used for the production of antisera for human use and since Koch has proved the contamination of sera with infectious anemia virus, it behooves the manufacturers of biologic products to select horses from areas in which swamp-fever has not been observed. The symptoms of one of the veterinarians, who had eaten infected horse flesh and had accidentally injured himself with an inoculation needle, consisted of headache, severe enteritis with blood in the stools, general weakness, emaciation, general pallor of the face and mucous membrane, and fever varying from 39 to 40° C. On two occasions, over a period of three years, the blood or the serum of the patient infected several horses after an incubation of from 26 to 39 days. Passage of the infective agent from horse to horse is readily accomplished. Thus it is conclusively proved that the virus of equine infectious anemia persisted in the body of a human being for at least three years. Another veterinarian suffered from severe anemia, his blood fatally infected three horses. These observations should be kept in mind and, particularly in the regions in which swamp-fever of horses is still prevalent (North Dakota, Nevada, Arkansas, Louisiana, Wyoming and Mississippi Valley), it would be desirable to test the blood of patients with obscure anemias by inoculating it into horses.

DOG DISTEMPER

Dog distemper is a disease which can be transmitted to comparatively few animals. Until Nicolle experimentally inoculated a human being with the filtered virus and proved, by reverse injection of the man's blood, the persistence of the disease agent in the body without producing clinical manifestations, man was considered insusceptible. Is the explanation of Nicolle

correct? Did distemper originate as a disease of man which gradually, through hereditary transmission of a resistance, lost its pathogenic properties for man, only to be transferred to his intimate associate, the dog? Is it not unlikely that certain respiratory infections in man are due to distemper? What is the significance of the recent findings that human influenza may be transferred to ferrets, the most susceptible animals for canine distemper? One awaits with interest further studies which may deal with the solution of these intriguing questions

The various pock diseases as virus infections should be considered under the general heading of this paper. Suffice it to recall that small-pox and all the animal poxes, except fowl-pox, are very closely related. In fact, it is probably correct to accept them as identical, and the variations which have been observed as merely adaptations to the particular animal with which they are associated. Each will, by passage through the calf, revert to the primal type, the cow-pox or vaccinia. The latter, as everybody knows, is readily transmissible to man, particularly through hands of milkers.

PSITTACOSIS

In recent years a virus infection of birds, readily conferrable to man, has assumed a wide distribution in the United States. This disease is known as *parrot fever* or *psittacosis*.

The single and group infections, which followed the exposure to South American and African parrots previous to 1929, attracted little attention. As a part of the great pandemic which followed the distribution of diseased parrots from Argentina and Brazil, an extensive outbreak of psittacosis made its appearance in November 1929. Armstrong placed on record 74 foci of infection which gave rise to 169 cases with 33 deaths from November 23, 1929 to May 7, 1930. Today it is fully realized that birds other than South American parrots were involved in the epidemic of 1929 and 1930. In fact since December 1931, it is definitely proved that psittacosis is a common infection in the breeding establishments of California. The commercial distributions of shell parrakeets (*Melopsittacus undulatus*) throughout the United States has resulted in at least 156 human infections and a mortality of 30, or 19.2 per cent. Until the avian disease has been eradicated, it is not unlikely that physicians will have an opportunity to encounter this disease. A somewhat detailed review of the present day knowledge appears justified.

The Infective Agent During the pandemic of 1929-1930 the virus character of the psittacosis disease agent was established by independent workers in England, Germany, the United States and France. Of particular importance was the discovery by Krumwiede, McGrath and Oldenbusch that the virus is readily transmitted to mice. The bacillus or *Salmonella psittacosis* has not been found in the course of the various studies conducted during recent years. In fact the extensive studies by Meyer and Eddie on several hundreds of infected shell parrakeets, and on the sputums

and organs of patients have proved the filterability of the disease incitant responsible for psittacosis. The virus is readily transmissible to white mice and various species of birds, in particular ricebirds and canaries. The fairly characteristic lesions produced in these animals are, as a rule, sterile but on microscopic examination reveal minute, Gram-negative ovoid or spherical bodies arranged in pairs and clusters. These corpuscular elements described independently by Levinthal, Cole, and Lillie are known as the L C L bodies or "*Rickettsia psittaci*". Their constant presence in definitely virulent material from different sources and the fact that filters with a pore width of less than 1.9μ usually retain the virus and thus indirectly define the particle size of the L C L bodies are facts in favor of the interpretation of the minute corpuscular elements as the infectious agent of psittacosis. In the diagnosis of parrot fever the L C L bodies possess the same value as Negri bodies in rabies. The virus is quite resistant to glycerine and under certain conditions to desiccation. However, it is readily destroyed by heat. In general, a strain of virus isolated from a parrakeet or a sputum may be passaged every six days. There is a tendency for certain strains to increase in virulence by passage in mice, but the virus does not become "fixed".

Birds Susceptible It is now fully appreciated that not only parrots and parrakeets are susceptible to psittacosis but that the canary (*Serinus canaria*), bullfinch (*Pyrrhula vulgaris*), nonpareil (*Cyanospiza cyris*), Java sparrow (*Padda oryzivora*), cockateel (*Leptolophus hollandicus* Kerr), Bengalese (*Uroloncha acuticauda*), Pekin robin (*Liothrix luteus*) and even the common fowl (*Gallus gallus*) may contract the infection by exposure. Recent observations leave no doubt that parrotlets (*Psittacula conspicillata* and *Psittacula spengeli*) and conures (*Eupsittula pertinax*) imported from Colombia and the native shell parrakeet or budgerigar from Australia may harbor the virus in the spleen and liver.

Disease in Parrakeets Shortly after the discovery of human psittacosis traced to California bred and raised shell parrakeets, a survey of the responsible aviaries was instituted. Visibly sick but mostly clinically healthy birds were autopsied and their organs, mostly spleens and livers, were tested for virus by intraperitoneal injections of mice. In acutely diseased birds the autopsy findings are as follows: A few drops of mucus on the ceres (nasal openings), a clean or soiled anus, thin, atrophic pectoral muscles, a large, heavy and tough, slightly saffron to ochre colored liver, occasionally (in about 10 per cent) studded with fresh or partially healed necroses and infarcts, slightly enlarged and congested spleen, rarely a few consolidated patches in the lower portions of one or both lobes of the lungs. The virus is readily demonstrated in the blood, brain and parenchymatous organs but not always in the nasal mucosa or content of the cloaca. The majority of birds examined, over 5,000, were the visibly healthy, well nourished shell parrakeets which had been chloroformed. The autopsy findings were essentially negative with the exception of a slightly or definitely enlarged spleen.

which quite regularly contains the virus. The degree of latent psittacosis in shell parakeets may be readily predicted by the percentage of spleens exceeding in diameter the normal average of 1 to 2 mm. Aside from the spleen and liver, the virus may be found in the ovaries and even the eggs. It is, therefore, not unlikely that the psittacosis virus may be transmitted congenitally.

Fifty-four, or 52 per cent, of 104 aviaries on which tests were made housed budgerigars with latent psittacosis. The percentage of virus carrying birds varied from 10 to 90 per cent. The virus leaves the body of the parakeet (or other birds) by way of the cloaca and the nasal mucus. The cloacal content is very rich in virus when the birds exhibit signs of diarrhea or polyuria. In the course of these tests on the elimination of the virus it was found that the livers and spleens may be non-infectious, while the nasal mucosa may produce typical psittacosis lesions in mice. Obviously, recovered birds may harbor the virus in the nose for an indefinite period. The infectiousness of a parakeet with psittacosis may be readily determined by placing in the same cage a pair of highly susceptible Java ricebirds.

Observations extending for several years have shown that avian psittacosis passes through an aviary about as follows. Many of the immature shell parakeets contract the infection early in life, the disease is rarely fatal. Within one and a half to five months the birds may recover completely and possess a sterile immunity. The recovery from the infection may be indicated by an enlarged spleen. Young parakeets may succumb to a relapse when transported in crowded cages or transferred into a cold climate. They are usually shedders of the virus and they may not only infect cage mates but human beings as well. Mature birds, eight months or older, are much more resistant and are seldom, if at all, involved in human outbreaks. Some may acquire a symptomless infection when exposed to shedding birds while others are entirely non-susceptible. The nature of this resistance is as yet unknown, it may be the result of a silent infection, or the result of a hereditary or maturation immunity. As far as preliminary studies indicate, the resistance is not associated with neutralizing humoral antibodies. Although the number of virus carrying birds and the danger of transmission of the infective agent to man progressively decrease with the age of the birds, it must always be remembered that the *incubation time* or the period which elapses between the injection of a shell parakeet with virus or the exposure to carrier birds may be from 41 to 106 days. A small percentage of the old breeding birds, cocks and hens, continue to harbor the virus and thus maintain the disease in the aviary. While the breeding operations are discontinued, deaths from psittacosis may entirely cease, but as soon as they are resumed, the malady may reappear and spread among the young birds.

Human Psittacosis In table 1 are presented the single cases or house epidemics which have been observed in the United States and Canada since 1929. One hundred and fifty cases had direct or indirect contact with diseased shell parakeets either in California or in other parts of the United

States and Canada to which this species of bird had been shipped During the same period infections, due to exposure to parakeets from Cuba, the "Orient," Yokohama and Holland, have been recorded In two, possibly three, cases the psittacosis infection was conveyed by canaries At least three, in all probability six, cases were secondary human to human transmissions

TABLE I

Psittacosis in the United States and Canada Due to California Parakeets and Canaries

| | | |
|--|----------------------------------|--|
| December 1929 | San Francisco, Calif | 1 case |
| January 1930 | Kansas City, Mo | 2 cases |
| March 1930 | Victoria, B C | 1 case |
| February 1931 | Milwaukee, Wis | 1 fatal case |
| February 1931 | Mantowoc, Wis | 1 fatal case |
| October 1931 | Los Angeles, Calif | 1 case |
| November 1931 | New York, N Y | 3 cases with 1 death |
| November 1931 | Los Angeles, Calif | 1 case |
| November 1931 | Portland, Ore | 2 cases, 5 suspects, 2 deaths |
| December 1931 | California | 13 cases with 6 deaths |
| January 1, 1932 to December 31, 1932 | California | 39 cases with 4 deaths 2 cases due to contact with canaries |
| January 1932 | Klamath Falls, Ore | 1 case |
| May 1932 | Chicago, Ill | 1 fatal case |
| July 1932 | Chicago, Ill | 3 cases with 1 death |
| August 1932 | Coloma, Mich | 1 fatal case |
| September 1932 | Several Counties in Minnesota | 19 cases, 8 suspects, 1 death |
| October 1932 | Boise, Idaho | 1 case |
| October 1932 | Malden, Mass | 2 cases with 1 death |
| October 1932 | Troy, N Y | 2 cases |
| October 1932 | Madison, Wis | 12 cases |
| October 1932 | Chicago, Ill | 1 case |
| January 1933 to December 1933 | California | 10 cases with 4 deaths |
| May 1933 | Sioux Falls, S D | 1 case |
| July 1933 | New York, N Y | 1 case |
| September 1933 | Minnesota | 1 case |
| October 1933 | Connecticut | 2 cases with 1 death |
| January 1934 | New York, N Y | 1 fatal case |
| February-March 1934 | Pittsburgh, Pa | 6 (5) fatal cases (?) |
| | Total | 130 cases 13 suspects and 30 deaths or a mortality of 19 per cent |

Cases Due to Parakeets from

| | | |
|----------------------------|----------------|--------------------------|
| <i>Orient</i> | | |
| April 1930 | Vancouver, B C | 9 cases |
| <i>Yokohama</i> | | |
| June 1930 | New York, N Y | 1 case |
| <i>Cuba</i> | | |
| January 1931 | New York, N Y | 5 cases |
| <i>Holland and Germany</i> | | |
| February 1932 | New York, N Y | with 2 deaths 2 cases |

The clinical manifestations, which were recognized as early as 1879 as a definite entity, have repeated themselves with remarkable regularity and uniformity. The composite clinical picture, as seen in the 50 cases concerning which histories or personal observations are sufficiently complete for analysis, is as follows:

The incubation time, although in many instances difficult to establish, is definitely known for 15 cases and varied from seven to 14 days after initial contact. In three cases, a single exposure occurred and the incubation period was seven, eight and nine days respectively. In human to human transmission the interval between the onset of the illness and the discharge of the nurse was eight and 13 days respectively. Quite important is the observation that in a third case the transfer of the virus from a fatal infection in a woman to her nurse was 30 days after discharge from the case or 39 days after the last exposure to infected parakeets. According to the published records, this must be considered an exceptionally long incubation period. The average is 10 days. As a rule, two to three weeks (average 14 days), but in a few instances three to four months, may lapse between the acquisition of the birds to the onset of the first case in a household (Ellcott and Halliday).

The onset has been mostly acute with chilliness, malaise and generalized pains, perhaps epistaxis. Prostration became marked during the first week and loss of appetite was always present. A temperature from 101 to 103° F or above presented itself and at first aroused no anxiety. Toward the end of the first week, however, the disease became more severe. Vomiting and, in about 25 per cent of the cases, diarrhea have been reported. A slight but irritating cough was constantly present. The headache was more intense and the patient presented the picture of a severe illness, ate little, constantly demanded fluids and lost weight. Restlessness, depression, tremor and bad dreams were followed by stupor and delirium and other encephalitic symptoms. The tongue was invariably coated a dirty brown and signs of a pharyngitis have been noted regularly. Abdominal distention and constipation were seen, and in one or two cases roseolae appeared on the skin. The temperature maintained itself at a high level with slight morning remissions in the fatal cases or it was definitely remittent, yet the pulse showed only a slight increase and stayed at the beginning below 100. Auscultatory examination at the beginning of the second week revealed no definite signs. Later, crepitant râles which moved from one area to another, usually beginning in the left lower lobe, were established. In the few cases in which roentgen-ray pictures were taken, the peculiar homogeneous, slightly opaque density and contour, and migrating location of the pneumonic process suggested the diagnosis of psittacosis. A cough, increasing in severity, was always present in the severe cases but it was only in 65 per cent of the patients. The sputum was or perhaps rusty and later definitely purulent. Respiration and pulse were increased.

definite area. Cyanosis and terminal pulmonary edema were seen in seven to 23 days after the onset. That the patient suffered from a very severe disease was amply attested by the pallor of the face, herpes labialis, blood-shot eyes, the semicomatose state only interrupted by delirious mutterings, restlessness and even violent excitement. Provided the pulmonary process was not too extensive, the patient's temperature dropped by lysis between the second to the fourth week. Recovery has invariably been slow and every patient complained of weakness and unsteadiness of gait for many weeks, even months. Relapses have been rare. Thrombotic-embolic processes were seen in one, possibly in two cases. Complicating bronchopneumonic infections, but in particular cardiac and vasomotor weakness, were responsible for the high mortality. A leukopenia (5,000 and 5,200) was noted in two of the 10 patients examined, while a normal count or a leukocytosis (17,200) was determined in the remainder of the group. A marked shift in the neutrophils to the left was always present. Although in about 15 per cent of the cases, the clinical picture resembled that of typhoid fever, the spleen was not palpable and the liver descended only in one or two patients. Aside from the severe cases, mild even ambulatory cases in old and young people have been observed. In fact the clinical observations differ in no way from those recorded in connection with the exposure to parrots. No explanation can be offered for the noteworthy fact that the same degree of contact and the same virus may induce a disease of a varying degree of severity. It is not unlikely that the susceptibility of man is quite variable and that a fair percentage may be immune or pass readily through the disease in a latent and subclinical stage. Treatment of the cases has been symptomatic with particular attention to the heart. Dr James B. Luckie has used leukocytic extracts hypodermically or intramuscularly. In some of the cases observed in the East, convalescent serums have been administered. The impression was gained that the disease was less severe but relapses were not prevented. Since weakly active neutralizing antibodies have been demonstrated in the convalescent human sera and since in some of the English cases antimeningococci serum and typhoid vaccine produced good results, it is quite likely that any agent which irritates the reticulo-endothelial cells is worthy of trial. However, mercurochrome in one case doubtless accelerated the fatal outcome.

In isolated cases, exposure to sick or dead parrakeets may induce clinical manifestations which in any one patient or in any stage of the malady are insufficiently characteristic to enable the physician to make a diagnosis. Various serologic tests for the enteric (*Salmonella psittacosis*) or undulant fever group of bacteria have been invariably negative, and it was merely the history of contact with parrakeets which finally aroused suspicion and led to a definite diagnosis. It may, therefore, be safely recommended that until the sale of non-infected birds can be guaranteed, it is well to be biased and to suspect psittacosis whenever a patient has recently brought psittacine birds or canaries into his or her household and suffers from severe influenza,

complicated by a migrating pneumonia. However, it is imperative that this suspicion or clinical diagnosis be confirmed, even though present laboratory methods frequently decide merely in retrospect. A definite laboratory diagnosis is also desirable for epidemiologic reasons. The majority of bird breeders, pet-shop owners, lovers of birds and even veterinarians still doubt the existence of such a disease as psittacosis.

The presence of the virus in the blood streams of patients has been established by Bedson and Western and by Meyer and Eddie. It has, however, been of little diagnostic value. In 28 clinical cases examined, the citrated blood of three patients infected mice when the blood was collected on the first, second and fourth days but not on the ninth, sixteenth or seventeenth days of illness. Since most of the patients rarely call a physician before the fifth or sixth day after the onset or at a time when the virus circulates irregularly, the mouse inoculation test with blood has been discontinued in California. However, the examination of sputums, first introduced by Rivers and Berry, has proved valuable. Since December 1931, Meyer and Eddie have tested the extracted, unfiltered but centrifuged sputums of 29 patients. A total of 42 sputum specimens has been examined. The virus was conclusively demonstrated in the sputum of 11 patients collected on the fifth, sixth, seventh, tenth, twelfth, fourteenth, sixteenth, twenty-third and thirty-seventh days respectively after the onset. One patient furnished a positive sputum on the fifth and on the tenth days but a negative one on the sixteenth day, while in a fatal case the excretion was infectious on the fourteenth, nineteenth and twenty-third days of the disease. In still another, the virus was found in the sputum on the tenth and thirteenth days. Seven of the nine cases observed in California since January 1933 had the nature of the infection proved by positive sputum findings. The failures to find the virus may be ascribed to the improper collection of the specimens late in the course of the infection. Since the virus is eliminated, irregularly repeated examinations on 24 hour specimens should be made. Microscopically, the secretion shows, as a rule, a few neutrophils, lymphocytes and large alveolar epithelial cells. The autopsy material of six human cases revealed the virus in the lung, spleen and liver in three, while in the fourth, the spleen and liver were devoid of sufficient virus to infect mice. From two autopsies the organ specimens were sent in the same container, consequently, separate examinations could not be carried out.

Epidemiology As might be expected, over 70 per cent of the human cases in California and elsewhere have been caused by newly acquired shell parakeets. The majority of infections resulted from exposure to sick and, subsequently, dead budgerigars. These observations, together with the laboratory findings on the epidemic birds, indicate that the sick or dead parakeets are more dangerous, largely on account of the liberal elimination of the virus through the nasal mucus and the droppings. The pathways of transmission of psittacosis from birds to man are probably twofold: (a) direct contact through the handling of the corpse of a bird which had died

of the disease, by feathers or excreta, by nasal discharge and through bite wounds, (b) indirect by the aerogenic route

There is no doubt that the droppings and nasal discharges of the birds are readily scattered by the flying motions of the birds, which are easily agitated by the persons who handle or approach the cage. Air currents may disseminate the suspended virus particles. The environment of an infected group or of a single parakeet may, therefore, be charged with virus and becomes a menace to human beings who may inhale it. It is, however, still a matter of conjecture whether the psittacosis virus in the droppings will regularly withstand prolonged drying and thus become dangerous. Furthermore, the possibility of infection by ingestion should not be ignored. Careful experiments are needed before a definite opinion can be expressed as to the importance of one or the other route. The high infectivity of the dispersed psittacosis virus, which resembles that of small-pox or measles, is shown in the histories in which a very short exposure occurred in a pet-shop where diseased birds were kept. It is, therefore, fully proved that, contrary to the general belief among the laity, actual contact or possession of parakeets is not necessary. A brief visit in a room with birds or sojourn in a baggage car transporting birds may be followed by disease in the susceptible.

Case to case infections, already reported as early as 1898 by Leichtenstern and subsequently by Hegler, Hatfield, Sturdee and Scott, Armstrong, Ellicott and Halliday, and others, have been definitely proved in three cases in the California series. The evidence at hand strongly suggests a human to human transmission in three additional cases.

An interesting characteristic of psittacosis outbreaks is the occurrence in house epidemics. In three instances, man and wife, in a fourth, brother and sister, and in the fifth, several guests of the same household contracted psittacosis. This feature of multiple cases in the same house may be of diagnostic value (Barros).

In this connection consideration should be given to the *attack rates* in general. It is well known that heavy exposure, as for example, the employees in pet-shops or visitors in rural households, may be between 65 to 100 per cent. In occasional exposures the rate may be as low as 6 per cent. At the beginning of the investigation in California the bird breeders and the persons associated with the bird fancying trade pointed to their apparent immunity and, consequently, denied the existence of psittacosis. Logically, it was reasoned that a disease, alleged to be derived from parakeets, would primarily attack those who are constantly in contact with these birds. Some credence was given to these arguments until systematic surveys not only proved the existence of psittacosis in aviary owners by laboratory tests, but revealed the fact that a history of a "severe attack of influenza with pneumonia" in bird breeders was occasionally elicited. It is naturally a matter of conjecture whether these "influenzal attacks" were true psittacosis or not. The fact remains that, of the 66 cases of psittacosis infections reported in California, 25 or 38 per cent were in owners of large or small parakeet aviaries or in members of their families.

The great epidemics of the past, in particular the pandemic of 1929–1930, occurred during the winter months. Epidemiologists, therefore, have expressed the opinion that the prevailing disposition to respiratory infections, during the colder months of the year, favored the spread of psittacosis. There is little support to this interpretation in the California data as shown in chart 1. It is true that in December 1931 and in January and

CHART 1

February 1932, many new cases were recognized. However, it must be appreciated that shortly before these dates, a great many infected young birds were freely distributed for the Christmas holidays and a vigorous investigative campaign assisted in the location of cases, which would otherwise have been missed. By contrast, no cases were seen or reported during the very cold months of November or December 1932, or January 1933, when a complete inter- and intrastate quarantine paralyzed the traffic of parrakeets. There is, therefore, no support to the contention that the cold winter of 1931–1932 precipitated the outbreak. Scattered cases reappeared when the handling and shipping of birds were resumed. Many cases were seen in September and October and severe psittacosis is not uncommon in midsummer. It may, therefore, be concluded that the seasonal fluctuations are only influenced by the prevalence of infected birds. Usually, in the fall and early winter, immature carriers, sick birds and their mates, which cannot resist the vigors of transportation, reach their destination and are readily

case, usually revealed one or two other milder cases, and thus helped to ameliorate the staggering mortality rate

Protective Measures Theoretically, psittacosis is a disease which could be easily controlled provided the public would appreciate the possible danger inherent in contact with birds, particularly of unknown origin. However, the love for pets so deeply rooted in human nature cannot be changed (Hasseltine). After nearly two years of struggle to accomplish some degree of protection by means of restrictive measures such as embargo and quarantine isolation, it becomes apparent that only one course is left open, namely, the systematic examination of the parrakeets by autopsies and laboratory tests and the destruction of the bird population of the aviaries housing infected budgerigars. This programme is now in process of execution. Time alone will tell whether it is possible to create breeding establishments free from psittacosis. Bird breeders and pet-shop owners, whose parrakeets have caused sickness and death, still declare in 1934 that psittacosis is an imaginary malady and the publicity a hysterical propaganda to injure their business.

In conclusion, it should be stated that the few examples were merely chosen to illustrate the complexities of a relatively new field of medicine. As a reservoir of human virus disease, the animal kingdom offers many intriguing possibilities and surprises.

UNDULANT FEVER¹

By JOSEPH L. MILLER, M D, F A C P, *Chicago, Illinois*

WHILE we are not justified in calling undulant fever a new disease in this country, there is no doubt that of late there has been a great increase in its incidence. This I believe can be explained only in part by new interest in and consequent recognition of this disease. The character of the fever curve in many cases is so unlike that of any known fever, that it should have attracted the attention of physicians in the past.

A few imported cases were reported as early as 1897. C. F. Craig in 1904 reported the first recognized case acquired in this country. In 1926 46 cases were reported in the United States and in 1932, 1505 cases. One-third of all those reported in 1932 came from three states—California, Missouri, and New York.

The first appearance of this disease in epidemic form occurred in southwestern Texas. In 1913 it appeared in epidemic form in southern Arizona. Eight years elapsed before another epidemic was observed, this occurred in Phoenix, Arizona, in 1921. All of these arose from infected goats. Because it was restricted largely to goatherds and those who handled the goats during the kidding season, it is probable that contact, rather than milk, was responsible. It is reported that 25 years previous to the Texas epidemic there was a peculiar epidemic fever which received the popular name of goat fever.

If other cases of fever resembling that seen in this disease were observed in this country, they have not been reported with sufficient accuracy to enable one to claim that they were cases of undulant fever.

This disease had long been present in epidemic form in the Island of Malta. Sir David Bruce (1886) who was assigned to determine the nature of this infection was able to obtain, in smears of organs obtained at autopsy, a microorganism which later proved to be the etiologic agent. It was not, however, until 20 years later that the goat was recognized as the host. This was a chance finding. Animal experimental work was planned and, as the goat was the most readily available animal, six of these were secured for this purpose. A preliminary blood examination was made and it was found that five of the six goats agglutinated the microorganism isolated by Bruce in high titre. B. F. L. Bang in Germany isolated a similar microorganism from aborting cows in 1897, but it was not until 1918 that its pathogenicity to man was recognized. In German literature Bang's name is attached to this disease. In 1914 J. Traum isolated a microorganism from pigs with epidemic abortion.

There has been, and still is, considerable confusion in nomenclature. Alice Evans demonstrated that the microorganisms isolated from these three

¹ Read at the Chicago meeting of the American College of Physicians April 20, 1934

sources were identical as far as could be determined by ordinary cultural methods. In this discussion, *Brucella melitensis* is used for the caprine, *Brucella abortus* for the bovine, and *Brucella suis* for the porcine strain. Huddleson¹ by using different dyes in the culture media was able to differentiate these three strains. It might be mentioned that a microorganism similar in character has been isolated from horses, chickens, sheep, and, in one instance, from an aborting bitch.

The bovine strain is responsible for undulant fever in most city dwellers through the ingestion of infected milk. In packing house workers and among farmers, the *suis* variety is not infrequent, probably from contact infections. Hardy, Jordan, Boots, and Hardy² found the *Brucella suis* in 20 cultures from farmers, only one of whom had had close contact with hogs. They also obtained *suis* cultures in four farmers' wives. Hardy claims the *suis* variety may be found in cow's milk. He also states that it is much easier to obtain positive blood cultures in *suis* infections than in infections with *abortus*.

Considerable work has been done to determine the incidence of diseased cows, by the use of the agglutination test. Apparently, there is considerable difference of opinion as to what titre can be considered positive. Hardy considers a 1-80 titre as positive and a 1-40 as suspicious. When testing herds in Iowa he found, in 1300 cows tested, 26 per cent positive and 8 per cent doubtful. Dietrich and Bonyne³ reported 36.7 per cent of 3000 cows in Los Angeles as being positive. Dr. C. P. Fitch (chief of the University of Minnesota Farm at St. Paul, Minn.) has tested all herds in scattered townships in Minnesota on the basis that a titre of 1-250 is positive and 1-150 suspicious. He has reported that 5.8 per cent of the cows in these areas were positive and 5.9 per cent suspicious. In 123 blood cultures from infected animals, only four were positive. In some herds he found over 20 per cent of the cows positive and 12 per cent suspicious. Starr⁴ states that in the course of the two years, 1931-1932, 45,285 dairy cows were tested. Ten per cent were positive. In an abstract of his report, from which this information was obtained, no mention was made of the titre.

Fitch claims that at least 85 per cent of abortions in cows are due to the *B. abortus*. The disease, he believes, is spread by introducing a new infected cow into a herd. Between pregnancies the infection is apparently latent, but becomes active in the uterus during pregnancy and the cow aborts in the fifth to seventh month. As not all infected cows abort, absence of abortion is not evidence that the herd is free of infection. A bull may become infected from a cow and such infection is usually followed by orchitis.

The placenta and amniotic fluid are heavily infected and also the vaginal discharge which continues for about three weeks after abortion. It is Fitch's opinion that cows become infected from forage that has become contaminated by the amniotic fluid or vaginal discharge of diseased cows.

Calves nursing from infected mothers rarely show any evidence of infection, although the germs may be found in the feces. These discharges are probably another means of contaminating forage. It is the general opinion that the cow does not develop an immunity, that the disease is chronic with a latent period between pregnancies. Fitch states that in examining milk he has found that the gravity cream is most likely to contain the microorganism.

INCIDENCE IN MAN

Four years ago Dr. A. V. Hardy, under the auspices of the National Institute of Health, made a survey of the entire state of Iowa to determine the incidence of undulant fever. He found 375 active cases widely disseminated throughout the state. Iowa is an agricultural state and 42 per cent of the inhabitants live on farms. In 10 instances he found more than one case in a family. In one instance an entire family of nine were infected. Seventy-seven per cent of the cases were males and 44.7 per cent of these were farmers. Among the women infected, 66 per cent were in farmers' families. Packing house employees showed the highest incidence. In a group of 100 positives who had no direct contact with live stock or fresh meat, it was presumed that the infection was acquired from raw dairy products. The disease was practically equally distributed between the two sexes—51 per cent male and 49 per cent female. The high incidence of males among farmers speaks strongly for the fact that the infection is acquired by direct contact.

Carpenter and Boak⁵ determined that guinea pigs were easily infected by gently applying a culture on the bare skin at the base of the animal's ear. They found that infection with the porcine strain through this channel was more readily attained than with the bovine strain. When taken by mouth, the animal is more readily infected with the bovine strain. In the group where the infection took place, presumably by direct contact, 29 positive blood cultures were obtained and 24 of these were the suis strain. Attention has already been called to the greater ease with which blood cultures can be obtained in suis infection. From these observations, we may conclude that milk or the handling of raw meat is not the sole manner in which infection is transmitted.

Studies have been made to determine by the agglutination test the incidence of this disease in certain occupations. These results are of limited value because investigators have not been able to arrive at definite conclusions as to the minimum titre that may be called positive. If such a test is positive, it means only that the patient at some time has been infected.

Dible and Pownall⁶ made a study of the agglutination test in packing house employees working on sheep, pigs, and cattle. They considered a titre of 1-40 positive. They found the highest incidence in those working with cattle, second, sheep handlers, and the lowest incidence in those working with hogs. Consequently, this indicates that infection may come from contact with sheep.

Veterinarians frequently show a high incidence of positive tests. In the great majority of those with positive tests there is no history of illness. There is abundant evidence that the agglutination test may be positive in the absence of any previous clinical manifestations. Huddleson and Johnson⁷ tested 49 veterinarians. Of these, 57 per cent were positive and 26 per cent, in addition, had a positive agglutination in a titre of 1-100. Therefore, the total of positive or suspicious equals 83 per cent. Only three gave a definite previous history of undulant fever.

Thomsen⁸ made a complement fixation test on 65 veterinarians and found 84.6 per cent positive. In none of these was there a previous history of infections.

A group of 18 veterinary students was examined—all were negative. Five months after entering practice 83.3 per cent were positive. In 16 bacteriologists working with *Brucella* 63 per cent were positive. In a group of 29 farmers 39 per cent were positive. In a group of 20 butchers 20 per cent were positive. As the complement fixation test alone was used on all this group, it is unwise to compare the results with those obtained by the agglutination method.

There has been some suspicion that the test may be positive in patients with typhoid fever. Bayne-Jones⁹ made agglutination tests on 180 patients reported to have typhoid fever and all were negative.

There are a number of reports where all sera sent to municipal, state and private laboratories for Wassermann or agglutination tests have been tested by complement fixation or agglutination for evidence of *Brucella* infection.

Sasano, Caldwell, and Medlar¹⁰ examined 1000 specimens by complement fixation—4.9 per cent were strongly positive, 4.7 per cent were weakly positive. In the agglutination test 4.1 per cent were positive in a titre of 1-45 or higher and 3.6 per cent positive in a titre of 1-15. In the 49 who gave a strongly positive complement fixation test, 36 also gave a positive agglutination. Four sera that gave a positive agglutination test in 1-45 to 1-135 gave negative complement fixation tests. Only five sera came from patients with clinical undulant fever.

Ruth Gilbert and Marion Coleman, in the laboratory of the New York State Health Department, examined 848 sera submitted for Wassermanns—0.4 per cent gave agglutination in 1-80 or higher. In 1186 sera submitted for agglutination test for typhoid 5.9 per cent gave a positive agglutination with *Brucella*, indicating that undulant fever may be mistaken for typhoid. In 1186 sera submitted as possible undulant fever, 11.5 per cent were positive. Just how many in this group were proved to be undulant fever is not known.

Meyers¹¹ in Nebraska tested 1000 sera submitted for Wassermanns. Of these 4.3 per cent were positive.

Hardy in his monograph has a very interesting report on agglutination tests on sera from various sources. These specimens came from the Iowa

State Laboratory and included sera for Wassermann and Widal, also sera from tuberculosis sanatoria, Iowa packing house employees, apparently healthy veterinarians, and from the Chicago Board of Health Laboratory. The sera from Iowa, submitted for Wassermanns, showed 9 per cent positive in a 1-20 titre, the sera from Chicago showed 1.5 per cent positive—showing the higher incidence of positive sera in Iowa. In the specimens submitted for Widal from Iowa 4.4 per cent were positive in a dilution of 1-20, specimens from 85 veterinarians showed 7.5 per cent positive in a dilution of 1-20, and 4.2 per cent positive in a dilution of 1-40—again showing a higher incidence as a result of contact infection. Inmates of a tuberculosis sanatorium showed 3.1 per cent positive in 1-40 and 2.9 per cent positive in 1-160 or higher—this might be accounted for by milk from an infected herd. The consumption of an unusual amount of milk would also increase the probability of infection. There are other reports showing an increased incidence of positive agglutination tests in tuberculosis patients. In the sera from 150 healthy packing house employees, he found a definite increase in positive titres—26.4 per cent were positive in a titre of 1-20 or more, 18.4 per cent positive in a titre of 1-40 or more, 7.8 per cent positive in a titre of 1-320 or higher, 1.3 per cent positive in a titre of 1-2500. The frequency of positive tests in high titre in people probably infected, but without present or past clinical history of any infection, indicates the restricted value of the agglutination test in determining the presence of an active infection.

A most interesting observation has been reported by Dooley¹² namely, that during an epidemic many of those using the infected milk may show high agglutination titre without symptoms. His observation was made in an Eastern boys' school where raw milk, from a private herd, was used. In 1925 epidemic abortions appeared in the herd, 12 cows aborting. Following this, any boy who had fever was given an agglutination test and this test was also given to many boys without fever. All tests were negative up to November 22, 1930. On that date one boy developed undulant fever and shortly after this a second boy. Investigation showed that one cow aborted on November 13 and that her milk was not used until November 18. This cow and four others which showed positive agglutination tests were removed from the herd and all milk was pasteurized. Following this, all the boys (232) and 31 adults were tested for undulant fever by the agglutination test—109 or 41.3 per cent were positive. 62 in a titre of 1-10 to 1-40, 32 in a titre of 1-80 to 1-160, 6 in a titre of 1-320 to 1-640, 5 in a titre of 1-1280 to 1-2560, and 4 in a titre of 1-5120 to 1-12,000. None of these boys had fever or were ill. The highest point in agglutination titre in this group was reached in January and February and after this the titre gradually fell. Eleven of those boys who had a titre of 1-10 to 1-40 later developed acute fever, chicken-pox, pertussis, sore throat, or febrile reaction after protective inoculation to typhoid. This was followed by an immediate rise in the agglutination titre. In one case

it rose from 1-80 to 1-640 This observation is of interest in that it shows the effect of an infection or febrile reaction on the specific titre

We may draw the following conclusions from this observation

First Only 2 per cent of those infected had symptoms, the others were unaffected by the infection If this be true, generally not more than 2 per cent of infected individuals are ill

Second A later mild febrile reaction may greatly increase the agglutination titre and might mislead the clinician into making a diagnosis of active undulant fever

From a diagnostic standpoint, it is important to know how long a positive agglutination test may persist There are several observations on this point which indicate that within six months, in some cases, the titre may be negative In one series of 45 cases reported by Hardy, 30 were still positive in 1-40 after 12 months

ONSET AND SYMPTOMS

The incubation period varies from five to 15 days

I know of no other acute infection in which there may be such a variety of symptoms, nor one in which there is such extreme variation in intensity and duration The onset may be so mild, and the symptoms so insignificant, that the person is unaware that he has been ill On no other basis can we explain the positive agglutination in people exposed to infections, but without any history of illness The onset may be acute, with chill and those symptoms common to acute febrile diseases The high fever may continue with intermissions for many years The outstanding symptoms are a septic type of fever with frequently recurring chills and drenching sweats, especially at night Very frequently, in fact an almost constant symptom, is arthralgia which in some cases may lead the physician to suspect he is dealing with an acute arthritis Frequently there is abdominal distress usually recurrent in character, which may be mild or severe and often localized A considerable number of patients have been operated upon for appendicitis or cholecystitis

The type of fever is extremely variable except that it always shows considerable daily fluctuation The typical textbook wave-like undulating fever is not common When present, it may persist throughout the course of the disease or be present inconstantly Only rarely does the fever resemble typhoid, as the daily variation is more marked The high septic type of fever may suddenly drop to normal, may remain so for days or for weeks, and then abruptly (often with a chill) re-assume its former characteristics Not all patients, however, have this characteristic drop in temperature In four of the seven cases I have seen, such drops in temperature have been noted In one case, where the disease is now in its seventh year, the patient has had three cycles when the temperature disappeared for months In one of these cycles the patient was afebrile for six months and gained 20 pounds in weight The presence of this type of fever is not

observed in this country in any other disease and, when present, is of high diagnostic import. Rat-bite fever may be intermittent, but is quite different as it has one-day fever with three- to five-day afebrile periods.

Excessive sweats, without great impairment of the patient's appearance of well being, also are of diagnostic value. In the long continued cases the patients do not show the typhoid facies. It is true that they may lose in weight, but this is due to the high fever and consequent increased basal needs rather than to anorexia. Delirium is extremely rare, usually transitory and associated with hyperpyrexia. There may be high fever, but very moderate evidence of toxicity. The physical appearance of the patient may have high diagnostic significance.

Joint disturbance is another almost constant symptom. It has been present in all of my cases. There is subjective pain and tenderness, but no swelling in the mild cases. On the other hand, the joint manifestations may be so outstanding that they resemble those of acute rheumatic fever. If the patient has an afebrile period, the joint disturbance subsides in a large measure. In one of my cases the joint changes in the fingers had the characteristic spindle appearance seen in chronic rheumatoid arthritis and the condition had been so diagnosed. An intermission of the fever was followed by a disappearance of the joint swellings.

Suppuration of the costo-sternal and costo-chondral junction has been reported. Kulowski and Vinke¹³ reported as a complication a suppurative spondylitis. Feldman and Olson¹⁴ have observed similar changes in hogs affected with this disease and have obtained a pure culture of *Brucella* from the pus.

Gastrointestinal symptoms of a peculiar character may be present. Nausea may be a symptom in any severe infection and may be observed in patients ill with this disease. However, the symptom that has some diagnostic significance is pain, intermittent, usually somewhat localized, but not confined to any particular part of the abdomen. When the pain is present there is localized tenderness. It has been reported that this symptom is more frequently present early, but I have seen it present in a case where the disease was in its eleventh month. The presence of such a recurrent pain has diagnostic significance. Simpson and Bowers¹⁵ have reported a number of patients with unrecognized undulant fever who have been operated upon for appendicitis or cholecystitis. The true cause of this pain has not been explained. An initial diarrhea has been reported, whether or not this ever persists, I have not been able to determine.

A prolonged septic type of fever, often with intermissions, arthralgia, profuse sweating, and intermittent gastric distress—when all are present—make it highly probable that the patient has undulant fever, even in the absence of a positive agglutination. Various complications may appear in the course of the disease, such as mastitis, oophoritis, and orchitis. One case with liver abscess has been reported and several cases with acute cholecystitis.

The pulse usually varies directly with the temperature. The spleen is usually, but not always, palpable. A slight, circumscribed macular or papular eruption has been described. Acute endocarditis, due to the *Brucella*, has been reported. As a result of prolonged fever, myocardial changes may develop and become manifest in the form of acute dilatation. In one of my cases, the patient developed acute dilatation of the right heart after eleven months of fever, without any preceding exertion to explain it. She recovered and at present has a competent heart. This same patient had also a fibrinous pericarditis.

LABORATORY FINDINGS

There is the usual secondary anemia. The leukocytes may be normal, or slightly increased in number, or there may be a leukopenia. In one of the cases in my series, during an unusual hyperpyrexia, the leukocytes reached 33,000. Considerable stress has been laid on the relative or absolute decrease in the polymorphonuclear cells. In patients with moderate leukocytosis, the percentage of mononuclear cells may equal the polymorphonuclear. This finding is of value when present, but it is not constant. One patient in my series never showed these blood changes.

Blood cultures when positive establish the diagnosis. Unfortunately, positive cultures can be obtained in only about 25 per cent of cases. So important is a positive blood culture that if, in a clinically suspicious case, it is negative it should be repeated several times.

Agglutination Test In the absence of a typical clinical picture much stress has been placed upon the agglutination test. From observations recorded in this paper we can readily see the fallacy of accepting such a test as conclusive. The epidemic in the boys' school showed that those infected, but free from clinical manifestations, had a great increase in titre during a febrile reaction, due to any cause, which might lead a clinician to conclude that he was dealing with active undulant fever. Furthermore, it has been shown repeatedly that patients with this disease may have a positive blood culture and negative agglutination, or agglutination in very low titre. On the other hand, if we accept low titres as positive, we will find a considerable number of patients, especially in certain vocations, who as a result of a symptomless previous infection, will give agglutination in low titre. The lesson to be learned from this is not to accept a positive agglutination if the patient's symptoms are not in accord with this diagnosis. If the patient's condition resembles an undulant fever clinically, do not abandon your clinical diagnosis even when there is a negative agglutination test, but continue to get repeated agglutination tests and blood cultures. Two of the patients in my series (one in whom the disease has been present for six years, the other, in whom it has been present for 11 months) clinically were cases of typical undulant fever. Early repeated blood cultures and agglutination tests, made by highly competent laboratories, were negative. Finally, after repeated agglutination tests, one of

the patients showed positive in 1-160, but a week later the agglutination test was again negative. The other patient, after repeated negative tests was positive in 1-80, then again negative, and later again positive. This same phenomenon has been observed in the Widal test for typhoid. Another patient in my series showed the first positive agglutination test in the seventh week of the disease. It is obviously impossible to determine the minimum titre that may be pronounced positive.

It has been reported that the failure in the agglutination test might be due to the presence of different strains of *Brucella*. Hardy has checked up on this by using 46 strains, including both abortus and suis, and has found no variation in titre beyond the limits of experimental error. He occasionally found a recently isolated strain to be more resistant to agglutination, but this resistance disappeared after the fourth sub-culture. Marked zone phenomena have been observed. High titres may be positive with low titres negative.

Complement fixation test and intradermal tests are open to the same criticism and are, I believe, less dependable than the agglutination test.

The reduction in the ratio of the polymorphonuclear cells in the blood may be of great diagnostic value when positive, but of little value when negative.

DIAGNOSIS

No attempt will be made here to discuss differential diagnoses. This has already been well done by others. From my limited experience, I believe that the diagnosis may be more difficult than in any other acute infectious disease. The recognized cases probably constitute only a small percentage of the persons infected. I only wish to emphasize the importance of accurate bed-side observation, using the laboratory as an aid.

DURATION OF THE DISEASE

There is wide variation in the duration of the disease. The febrile period, in clinically recognized cases, may last only two or three weeks. In other cases the disease takes on a chronic form and continues for many years.

MORTALITY

The mortality, if we were able to diagnose sub-clinical cases, would be extremely low. In recognized cases it will average about 3 per cent.

THERAPY

Preventive methods are now limited largely to the elimination of infected cows and the pasteurization of milk. Pasteurization is effective when properly applied. There is still considerable difference of opinion in regard to the titre in cows that may be considered positive. Probably cows vary in this respect the same as man. If these two methods of pre-

vention were carried out efficiently, we would still have the problem of contact infection, the elimination of which offers apparently insurmountable difficulties

Experimental efforts to immunize cows against this disease have not been successful

Active Treatment Regarding active treatment one is inclined to believe with Hardy that "We find no record of a properly controlled systematic investigation in therapy" For this reason different forms of treatment will not be discussed in detail The not infrequent sudden termination of the disease may readily deceive the therapist

Vaccine therapy in cows, according to Fitch, is of no value In man specific vaccine therapy is at present at a very low ebb When vaccines are given in large doses subcutaneously, sufficient to cause a marked rise in temperature, or intravenously, with consequent febrile reaction, if results are obtained they are probably due to foreign protein therapy rather than the result of a specific vaccine

Chemotherapy has failed

Experimental work with serum therapy in guinea pigs has at best been only moderately successful (See report of work of Gwatkin¹⁰) Foshay has recently obtained a serum, by prolonged immunization of goats, which is promising In a single case where I used it there was a prompt and permanent disappearance of the fever

The literature contains several favorable reports following the use of typhoid vaccine intravenously There are also some reports indicating favorable results following the use of arsphenamine

With no specific treatment of proved value, general care of the patient is probably the most rational form of therapy Bed rest, fresh air, nourishing food, with indicated symptomatic treatment, are important

SUMMARY

The incidence of this disease is probably much higher than reported cases would indicate In blood submitted for the Wassermann test about 5 per cent of specimens show agglutination in moderate titre to *Brucella* In many active cases it is impossible to get a positive agglutination test unless the test is repeated at frequent intervals In long-continued cases the clinical signs and symptoms may be relied upon to make the diagnosis

The best preventive measure is pasteurization of milk

Among farmers the porcine type of infection is often found

There is no proved satisfactory method of treatment

GONOCOCCAL ARTHRITIS. A CLINICAL STUDY OF 69 CASES *

By CHESTER S KEEFER, M D , F A C P , and WALTER K MYERS, M D ,
Boston, Massachusetts

ONE of the commonest causes of acute and chronic arthritis is gonococcal infection. In many patients the diagnosis is a task of no small difficulty inasmuch as the arthritis may appear some weeks, months or years after the primary infection and, indeed, it may manifest itself for the first time after the original site of infection has healed entirely. In view of the frequent difficulty in diagnosis, we have analyzed the clinical features and course of the disease in 69 cases of gonococcal arthritis which we have observed during the past three years, in an attempt to emphasize a number of features which were helpful in establishing a diagnosis. In addition, we present data regarding prognosis in this disease.

Before proceeding with the detailed analyses of the cases, it is well to recall the pathologic features of the joint lesions in gonococcal arthritis. Elsewhere, Keefer, Parker and Myers ¹ have described the histological picture of the synovial membrane in gonococcal arthritis. An appreciation of the changes is helpful in understanding the variations in the clinical picture and course of the disease so far as the joints are concerned. When there is pain, periarticular swelling and exudation of non-infected synovial fluid into the joint cavity, the pathologic process is confined for the most part to the synovial connective tissue where there are collections of polymorphonuclear leukocytes, lymphocytes and plasma cells about the blood vessels and between the strands of connective tissue. The cells upon the surface of the synovial membrane are intact and show no destruction. In these cases, it may be extremely difficult and, indeed, impossible to cultivate gonococci from the synovial fluid. In other cases in which the synovial fluid contains numerous cells and organisms, there is an extensive inflammatory reaction of the synovial membrane and underlying connective tissue. When such is the case the superficial cells of the synovial membrane are destroyed entirely, leaving only a layer of granulation tissue with newly formed blood vessels, many polymorphonuclear leukocytes and numerous gonococci. The deeper layers of the synovial membrane may not be involved extensively but there may be destruction of the cartilage and underlying bone with a resulting fibrous or bony ankylosis. The destruction of cartilage and bone may occur within a short period of time following the onset of infection, and this feature frequently aids in the discrimination of gonococcal arthritis from other types of

* Received for publication June 1, 1934

chronic joint disease. Figure 1 illustrates the bone destruction that may occur in the metacarpal bone within a period of three weeks.

The diagnosis of gonococcal arthritis was made from the following points: (1) A history of a recent or previous gonococcal infection of the genito-urinary tract. (2) The presence of a localized gonococcal infection as proved by symptoms, signs and bacteriologic examination. (3) The presence of gonococci in the synovial fluid or a positive gonococcal complement fixation test in the blood serum or synovial fluid. In the event of not being able to demonstrate gonococci in the synovial fluid, care was

FIG. 1. (1) X-ray examination of right hand showing a normal joint space of metacarpal-phalangeal joint of the index finger. (2) X-ray of the same hand taken three weeks later showing destruction of bone, loss of joint space of the metacarpal-phalangeal joint of the index finger.

taken to exclude other types of arthritis such as rheumatic fever and tuberculous arthritis. In no case, however, was the diagnosis of gonococcal arthritis accepted without at least finding a localized gonococcal infection or a positive gonococcal complement fixation test on the blood sera or synovial fluid.

ANALYSIS OF CASES

Age The age of the 69 patients varied from 18 to 70 years. Thirty-two of them were between 20 and 40 years.

Sex There were 58 males, 11 females.

Color Sixty-four were white, four were negroes and one was an Indian.

Previous Attacks of Arthritis Twenty-one patients had had a previous attack of arthritis, and of these, 14 were definitely gonococcal arthritis. Of the remaining seven, three were due to acute rheumatic fever, and in

the other four the etiology was uncertain, it was stated that no urethritis existed at the time of the previous attack

Previous Attacks of Gonorrhea Thirty-four patients had had more than one attack of gonorrhea, and in seven additional cases the presence of a previous infection was probable. Fourteen of these patients had had gonococcal arthritis with their former attack of gonorrhea. This is a fairly high proportion in such a small number of cases, but it bears out the previously observed fact that recurrent attacks of arthritis are common with reinfection due to the gonococcus.

Time of Onset of Arthritis in Relation to the Gonorrhea The evidence obtained as to the relation of the onset of arthritis to the stage of the initial lesion was not satisfactory in every case. This was due to the presence of a chronic genito-urinary tract infection of indeterminate duration or to inaccurate observations of the patients. In one, the arthritis began simultaneously with the appearance of an attack of urethritis, in eight, it appeared between 10 and 14 days after the onset of gonorrhea, in two, within three weeks, and in three, from two to six months. In the other cases the infection was either of indeterminate duration or there had been multiple attacks of gonorrhea so that the time relations could not be determined with accuracy. In three instances all traces of the local gonococcal infection had disappeared.

The observations indicate that arthritis may appear at any time after the onset of gonorrhea, commonly after reinfection, or rarely when the local genital tract lesion has disappeared.

Relation of Onset of Arthritis and Other Complications of Gonorrhea There were 16 patients with bilateral catarrhal conjunctivitis (23.1 per cent) and three with unilateral iridocyclitis. Inasmuch as we did not see the patients until after the arthritis appeared and as, in some cases, the conjunctivitis gives rise to very few symptoms, the precise time relations between the onset of the arthritis and the ocular complications were difficult to determine. In two cases, the conjunctivitis appeared at the same time as the arthritis, in six, it had been present from one to 10 days before the onset of the joint pains, and in the others it was present at the time of the first examination and its duration could not be ascertained accurately. The conjunctivitis commonly disappeared within two weeks and before the joint pains. In only one case were relapses observed, and this was associated with a recurrence of an iridocyclitis. The discharge from the conjunctivae was scanty in amount and consisted of mucus containing leukocytes, but in no case were gonococci recovered from the exudate. Simple conjunctivitis always disappeared without any permanent damage to the eyes. Three patients had unilateral iridocyclitis, and conjunctivitis. This was extremely painful and produced a lesion resulting in diminution of vision.

One patient developed endocarditis, in this instance the arthritis pre-

ceded the signs of endocarditis but it was not clear how long vegetations had been present on the valves before the signs appeared

Death occurred in four patients, in one there was an endocarditis, in another an intercurrent lobar pneumonia, in a third death resulted from a progressive gonococcal infection, and in the fourth there was a streptococcal septicemia

Type and Extent of Local Gonococcal Lesion Associated with Arthritis Of the patients with arthritis, 54 had prostatitis, 43 urethritis, 10 cervicitis, five epididymitis, one seminal vesiculitis, and one each an abscess of Cowper's glands, Bartholin's glands and Skene's glands. Three of the women were pregnant at the time of the infection, and in three no signs of a localized infection could be found. In men, it was the rule to find involvement of the posterior urethra and prostate when arthritis was present. In an occasional case, the onset of the arthritis could be definitely related to the extension of the local process to the prostate, epididymis or Cowper's gland

Symptoms and Clinical Course The first symptom complained of was usually pain in one or more of the joints, either the small joints of the hand, or the larger joints such as the knees or ankles. The pain was often first noticed to be dull and aching in character, exaggerated by motion, and then followed by swelling and redness. Of the 69 patients, the onset appeared after a respiratory infection in 10, and in these this history gave rise to considerable difficulty in diagnosis. The degree of swelling varied tremendously so that in 40 of the cases we were able to aspirate from five to 165 cubic centimeters of fluid from the joint cavities, and in 13 this was done more than once. The effusion into the joints varied in its duration, in 27 cases it diminished after one aspiration so that it was not necessary to do another, whereas in 13 it had to be repeated from two to 11 times. The pain was usually diminished markedly following aspiration of the joints

Very often there was localized tenderness of the joints, especially, as in the knee, about the attachment of the quadriceps tendon to the patella and about the edge of the tibia

Muscular atrophy in the neighborhood of the affected joints was observed in all cases, and in many it was extreme and out of all proportion to that which could be accounted for on a basis of disease alone

Relaxation of ligaments and dislocation were not observed, but the deformities and restricted motion were due to contracture of the capsular tissues

Joints Involved Sixty patients had a polyarticular arthritis, and in the other nine it was monoarticular. The joints that were involved are summarized in table 1. From this table it is seen that any or all of the joints may be attacked during the course of the infection. The olecranon bursa was involved once. A very common lesion when the ankles, wrists and metatarsal-phalangeal and metacarpal-phalangeal joints were the site

TABLE I
Joints Involved in 69 Cases of Gonococcal Arthritis

| Olecranon bursa | 1 | |

of infection was an associated tenosynovitis. This latter feature was outstanding in 33 cases and often it completely dominated the clinical picture. In one case, a localized tendon sheath abscess containing gonococci was seen.

Fever. An elevation of temperature above normal was observed in most of the patients. In some, it was of a few days' duration, in others, it was indeterminate and prolonged, varying from 99° to 100° or 101° F, and in a few cases reading as high as 102° to 103° F. In none of the cases was the temperature curve influenced by salicylates and there was nothing characteristic of the febrile reaction in the group as a whole.

Blood. The white blood cell count was increased in all cases, varying between 9,000 and 23,000 per cubic millimeter. The polymorphonuclear cells were increased and varied between 70 and 88 per cent. In the prolonged cases, an anemia frequently developed.

Sedimentation Reaction. The sedimentation rate was increased in all the cases, varying from 0.4 to 1.7 mm per minute according to the method of Ernstene and O'Rourke. This examination was of no specific diagnostic value as we² pointed out previously. It was, however, helpful in following the course of the active infection.

The course of the disease was so variable that diagnostic difficulties often arose. In the acute cases, the differentiation from acute rheumatic fever was sometimes difficult, and in the subacute cases, the discrimination from rheumatoid arthritis was necessary.

The differentiation from acute rheumatic fever was especially difficult in the cases presenting a history of the onset of the arthritis following a

respiratory or tonsillar infection. In these, the onset of the joint pains was often acute, and it was only by observing the lack of responses to salicylates and the absence of changes in the cardiovascular system by physical or electrocardiographic examination, and by finding positive evidence of gonococcal infection that one could be reasonably certain of the diagnosis. In the subacute or chronic cases, the diagnosis was made only after the evidence for gonococcal arthritis had been obtained by repeated bacteriologic and serologic examinations.

The presence of bilateral conjunctivitis, perichondritis, iritis or tenosynovitis associated with arthritis that is progressive and deforming was suggestive of a gonococcal etiology and often helpful in diagnosis.

Prognosis The prognosis in a given case of gonococcal arthritis is always difficult as far as the outcome is concerned. This is due, in part, to the extreme variation in the course of the disease and to a lack of information regarding the mechanism of recovery from gonococcal infection. Another factor of significance is the question of reinfection before the joint lesions have subsided completely. This was observed frequently and was followed in a large number of instances by an exacerbation of joint pains. In a previous paper,³ we called attention to the fact that in patients who showed organisms in the synovial fluid and a cell count above 40,000 the outlook was poor compared with those with a non-infected fluid and a lower cell count. Even in such cases, the outlook is not very good as far as complete recovery is concerned, since only 37 per cent of our cases recovered completely without any signs of joint disease.

It can not be denied, then, that gonococcal arthritis is a serious disease. Factors that will influence the outcome are (1) Severity of infection and reaction in the synovial cavities (2) Persistence of local infection (3) Reinfection.

Gonococcal Complement Fixation Tests These were done on the blood serum of 52 patients and on the synovial fluid in 27. Of these cases in which the blood was examined, 45 specimens were positive (80 per cent), two were doubtful and five were negative. Of the cases in which the synovial fluid was tested, 20 or 74 per cent were positive. The principal diagnostic value of the test was in the cases in which organisms could not be recovered from the synovial fluid, or in the cases in which it was not possible to find organisms in the local process. This was the case in 11 instances.

Synovial Fluid Information of considerable diagnostic value was obtained from examination of the synovial fluid, which was performed in 40 cases. For purposes of discussion they are divided into two groups, according as to whether the synovial fluid contained organisms or not. In the group of infected fluids, the total cell counts varied from 7,350 to 158,000 per cubic millimeter and for non-infected fluids from 1,800 to 78,250 per cubic millimeter. While the polymorphonuclear leukocytes predominated in both groups, they were usually higher in the infected than in

the non-infected group In the latter cases, there were more lymphocytes, monocytes and clasmatocytes In no instance, however, did they increase above 33 per cent The chemical examinations of the fluid, including total protein, sugar and non-protein nitrogen, yielded no information of specific diagnostic value The serologic examinations were detailed in the section dealing with the gonococcal complement fixation test

Comment From this analysis of 69 cases certain features require special comment They can be discussed more clearly by reporting illustrative cases We refer especially to the ocular complications, the presence of arthritis without evidence of localized genital infection, tenosynovitis, perichondritis and endocarditis

CASES WITH OCULAR COMPLICATIONS

CASE I

Case of Bilateral Metastatic Conjunctivitis, Tenosynovitis and Arthritis

A 31 year old white man was admitted to the hospital with the complaint of burning of both eyes and joint pains An acute gonococcal urethritis had been present for one month He had received anterior urethral irrigations of a 1-5000 solution of potassium permanganate Ten days before entry both eyes became inflamed There was intense burning and itching There was little exudate from the conjunctival sacs Repeated stained smears failed to disclose a gram-negative diplococcus The conjunctivitis improved following boric acid irrigations and instillation of 0.5 per cent zinc sulphate Seven days later, following a mild rigor, the left ankle became swollen, hot and tender The right knee and right sacro-iliac region also became painful

The patient had had an anterior urethritis due to the gonococcus nine years previously There were no complications at that time

On entry, the temperature was 99° F, the pulse rate was 90 per minute The patient was well developed and well nourished, and acutely ill Movement of the affected joints caused severe pain There was edema of both eyelids and photophobia The conjunctivae were only very slightly inflamed There was a small amount of pus which could be expressed from the urethra The prostate was tender, boggy in consistency and slightly increased in size There was much swelling, increased heat and tenderness of the tendon sheaths about the left ankle Movements of the ankle joint induced severe pain Flexion of the left knee caused pain Tenderness was elicited on pressure over the right sacro-iliac articulation

Stained smears of the urethral pus revealed numerous intracellular gram-negative diplococci The gonococcal complement fixation reaction on the blood was positive on three occasions The Kahn and Wassermann reactions were negative The leukocyte counts varied between 9,500 and 14,000 per cubic millimeter Roentgenologic examination of the pelvis, knees and ankles showed no bone changes

With local therapy the urethral discharge disappeared but the prostatic infection continued The lower back pain persisted About the left ankle, the increased heat and tenderness subsided gradually but slight swelling and pain on motion persisted Pain on motion of the right ankle subsided Swelling, redness and pain in the right fourth toe appeared the third week in the hospital, and later subsided somewhat The patient left the hospital three months after entry There remained slight tenderness over the right sacro-iliac articulation, slight swelling and tenderness about the left ankle and slight swelling and pain on motion of the right fourth toe

This patient illustrates, then, two common complications of gonorrhea, namely, arthritis with tenosynovitis, and bilateral metastatic catarrhal conjunctivitis. The latter complication is by no means infrequent, and occurred in 23 per cent of our cases. It is called metastatic catarrhal conjunctivitis in contrast to the purulent type which develops following the direct inoculation of the conjunctival sac with gonococci, and it must be carefully differentiated from this latter type since the prognosis in the two types is quite different.

While the metastatic conjunctivitis may be the only manifestation of a general infection, it is more often associated with other complications, such as arthritis, and for that reason its presence is of some diagnostic importance inasmuch as conjunctivitis is less common as a complication of other types of arthritis. It appears before, or simultaneously with, the arthritis. It is characterized by a bilateral injection and inflammation of the bulbar and ocular conjunctivae, with scanty mucoid discharge and slight subjective symptoms in comparison with the objective signs. The sequence of events in our cases was as follows. Following a localized gonorrhea, there appeared before, with or after the onset of arthritis a catarrhal inflammation of the ocular and bulbar conjunctivae. The upper lid was more often spared than the lower. In a few cases the lids were swollen and edema of the conjunctivae with chemosis of the bulbar portion appeared. The subjective symptoms were often minimal but burning, pricking, smarting, lacrimation and photophobia were frequent complaints. In all but three cases the process was benign, lasting about two weeks. In none of the cases were we able to recover gonococci from the exudate. The diagnosis was made on the presence of a gonorrhea, the absence of a history of infected material coming in contact with the eyes, the bilateral process, the mildness of the subjective symptoms in comparison with the objective signs, the scantiness of the exudate and the absence of gonococci.

In the three cases with iritis, the ocular manifestations were more severe. The following case illustrates the course of events in a man with iritis.

CASE II

Case with Iridocyclitis and Arthritis

A 30 year old white man entered the hospital because of painful swelling of the right knee and ankle and pain in the left knee. For two weeks, the patient had had mild lower back pain. Four days before entry, this disappeared, but there was redness, photophobia and lacrimation of the left eye. These symptoms subsided somewhat but there was blurring of the vision of the left eye. The right knee and right ankle had been acutely painful and swollen.

Gonococcal infection was denied. There had been a shrapnel wound of the right knee, with a subsequent operative procedure, five years previously. There were never any other joint lesions.

On entry the temperature was 100° F, the pulse rate was 100 per minute. The patient was well nourished and well developed. He appeared acutely ill. The conjunctiva, iris, pupil and fundus of the right eye were normal. The left pupil was con-

tracted, fixed and irregular, there was marked circumcorneal injection, the pupillary space was cloudy, the fundus could not be seen. There was no urethral discharge. The prostate was tender and boggy in consistency. The capsule of the right knee was distended. The right ankle was swollen over the dorsal and lateral surfaces. Both joints were limited as to motion because of the severe pain. There was an increase in local heat but no redness about either joint.

The increased synovial fluid in the right knee was aspirated the day following admission. Ninety cubic centimeters of yellow turbid fluid, containing 52,800 cells per cubic millimeter, were removed. Ninety-eight per cent of the cells were polymorphonuclear cells and 2 per cent were lymphocytes. Fluid reaccumulated so that aspiration had to be repeated two and, again, four days later. The cells numbered 26,450 and 9,900 per cubic millimeter, respectively. The polymorphonuclear cells made up 98 and 99 per cent of the total, respectively. No organisms were recovered from these fluids on culture. The gonococcal complement fixation reaction of the fluids, as well as the blood sera, were positive. The Wassermann reaction was negative in the specimens of fluid and blood sera.

Soon after entry there was swelling, pain and tenderness of the left wrist joint. Fluid did not recur in the right knee. The left wrist and right ankle lesions subsided gradually. One month after entry pain and tenderness over the sacro-iliac articulations appeared rather suddenly, to persist for six weeks. Following a vigorous prostatic massage six weeks after entry there was a sudden appearance of fluid in the left knee joint with an exacerbation of the iridocyclitis of the left eye. Ninety cubic centimeters of yellow cloudy fluid were removed from the left knee joint. This fluid contained 13,300 cells, of which 92 per cent were polymorphonuclear cells, 5 per cent were clasmotocytes and 3 per cent were lymphocytes. The culture of this fluid did not yield a growth of microorganisms. Ten weeks after entry the patient still complained of pain in both knees, particularly on motion. The left wrist was painful on motion and slightly swollen. There was moderate swelling but little pain about the right ankle.

Following treatment, the left eye at first improved with loss of pain and lacrimation, and the partial return of vision. The conjunctiva was not inflamed. The pupil was dilated and regular. There was a recurrence of the symptom of iritis six weeks after entry as noted. Ten weeks after entry vision remained somewhat impaired, but no other symptoms remained.

Smears of the prostatic secretion revealed numerous gram-negative intracellular diplococci. The leukocyte counts varied between 7,800 and 15,000 per cubic millimeter. Roentgenologic examinations of the articulations showed evidence of synovitis but no bony changes.

Treatment consisted of instillates of a 1 per cent solution of atropine and boric acid irrigations of the left eye, light prostatic massage, forced fluid intake, bed rest, rest of the involved joints, massage and muscle-setting exercises.

In this case, the iridocyclitis was extremely painful, interfered with vision and left its mark in that there was permanent damage to the eye. There were relapses of both the arthritis and iridocyclitis while under observation, the cause of which remains unexplained. Whether the rigorous prostatic massage was responsible for a relapse remains an open question.

The ocular complications of gonorrhea have been discussed at length by Byers⁴ in a most excellent and comprehensive monograph. He pointed out that the deep-seated congestion observed in some cases of conjunctivitis was often an expression of an inflammation of the interior structures of the eye. This is especially true when the uveal tract is involved, such

as we observed in the three cases of iridocyclitis. Byers emphasizes the fact that second and later attacks of uveitis are observed with recurrent attacks of gonorrhea. This also is true of attacks of arthritis.

CASES WITH TENOSYNOVITIS AND PERICHONDRITIS

CASE III

Case of Arthritis and Tenosynovitis without Evidence of a Localized Genito-Urinary Infection

A 21 year old man was admitted because of painful swollen joints. Five days before entry the patient sustained a slight laceration of the right thumb which required incision. Three days before admission he developed a sore throat, and swelling, pain, redness and increased local temperature of the knees and wrists. The following day, although the temperature was 104° F, the right knee and right wrist were asymptomatic. The left knee and left wrist continued swollen, red, painful and tender.

On entry the temperature was 98.6° F, and the pulse rate was 98 per minute. The patient appeared moderately ill. The pharynx was inflamed. The left knee was tender, hot and tensely swollen. There was evidently an increase in synovial fluid. The left hand and fingers were markedly swollen over the dorsal surface. Motion of the left hand and fingers or pressure caused considerable pain. There was no urethral discharge. The prostate was normal in size, shape and consistency. No prostatic fluid could be expressed.

The day following admission the synovial fluid of the left knee was aspirated. Eighty cubic centimeters of yellow cloudy fluid were removed with a cell count of 37,000 per cubic millimeter. The supra-vital preparation showed 86 per cent of polymorphonuclear cells, 12 per cent clasmatocytes and 1 per cent each of lymphocytes and monocytes. Two days later, the synovial fluid had reaccumulated and 80 cubic centimeters were removed. The cell count on this occasion was 14,300 per cubic millimeter, of which 94 per cent were polymorphonuclear cells, 3 per cent were clasmatocytes, 2 per cent were monocytes and 1 per cent was lymphocytes. The cultures of specimens of both these fluids yielded gram-negative diplococci which were identified as gonococci.

The gonococcal complement fixation reaction on the blood serum and synovial fluid during the first two weeks was negative. After the second week the gonococcal complement fixation reaction on the blood serum was consistently positive. The Kahn and Wassermann reactions were negative.

The swelling of the left knee did not recur following the second aspiration. However, the swelling of the dorsum of the left wrist and fingers persisted for two weeks before subsiding. Several superficial veins of the left forearm became thrombosed.

Treatment consisted of sedatives, bed rest, and splinting and local application of heat to the left wrist. The patient remained in the hospital for seven weeks. At the time of discharge there was limitation of complete flexion of the left wrist. There was no limitation of motion nor abnormalities of the left knee.

The outstanding features of this patient's illness were the absence of a history of gonorrhea, no clinical evidence of a urethritis, but a definite arthritis and tenosynovitis due to gonococcal infection. These observations emphasize the importance of a careful bacteriologic study of synovial fluid even in the absence of a history of gonorrhea or of the demonstration of a localized gonorrheal infection.

CASE IV

Case with Tenosynovitis and Perichondritis of Cricoid Cartilage Associated with Arthritis

A woman, 20 years of age, was admitted to the hospital complaining of pains in the joints of five days' duration. Two weeks before entry an abscess of the left Bartholin's gland appeared and three days later ruptured spontaneously. Four days before entry the right wrist became painful on motion and a swelling which was finally hot, red and very tender appeared on the dorsal surface of the wrist. The following day the left shoulder was sufficiently painful to prohibit motion of this arm. Two days before admission there was pain on swallowing and tenderness over the larynx. The left knee became painful the day of entry.

Four years previously the patient had been treated for gonorrhea for two months. Two years before the present illness there was an abscess of the left Bartholin's gland which ruptured spontaneously after one week. There had been no previous joint symptoms.

The patient was moderately obese and did not appear to be acutely ill. There was some injection of the pharynx. Pressure over the cricoid and thyroid cartilages caused pain, but there was no demonstrable swelling or redness. The dorsal surface of the right wrist was slightly swollen, red and tender. Motion of the right wrist and fingers caused pain in the area of swelling. Motion of the left shoulder, which was slightly swollen and tender, caused pain. There was tenderness over the left popliteal space.

Stained smears from the urethra and cervix contained numerous gram-negative intracellular diplococci. The gonococcal complement fixation reaction was doubtful on two occasions during the first week, and positive at the end of the second week of her stay in the hospital. The Kahn and Wassermann reactions were negative. The leukocyte count never exceeded 10,200 per cubic millimeter.

Soon after entry the palmar aspect of the right wrist became swollen and tender. Swelling and tenderness also appeared just above and posterior to the external malleolus of the left ankle. With rest in bed the symptoms subsided after 10 days. Three weeks after entry a small localized area of redness, tenderness and swelling appeared to the radial side of the distal end of the right ulna. On aspiration a small amount of purulent material was obtained which yielded on culture a gram-negative diplococcus. This was incised and drained. The patient was symptomatically improved at the time of discharge one month after entry.

This patient, then, illustrates two metastatic lesions of gonorrhea aside from arthritis, tenosynovitis which finally localized with abscess formation and a perichondritis of the cricoid cartilage.

Tenosynovitis is a particularly common complication of gonorrhea and, while it is usually an accompaniment of all types of arthritis, it occasionally occurs independently. For these reasons, its presence is often suggestive of the diagnosis of gonococcal infection. It was present in 43 per cent of the cases. (See table 1.) The tendon sheaths most frequently involved were those about the internal and external malleoli, and those over the dorsum of the hands and feet. In four patients, there was involvement of the tendons about the knee joints. Aside from these tendons, those of the palm of the hand and the Achilles tendon may be involved. (Strandberg⁵) The clinical features are quite striking, in that the skin over the tendon sheaths is swollen, hot, tense, shiny, and any movement or pressure of the affected part is accompanied by agonizing pain and discomfort.

Rarely, as in case 4, there is suppuration and it becomes necessary to incise and drain the affected part.

Perichondritis of the cricoid cartilage was a feature in case 4, and in one other patient. This complication is observed in an occasional case and one's attention is attracted to it by the patient's complaint of both painful and difficult swallowing. Pressure over the affected cartilages produces pain and discomfort, and lateral motion is particularly apt to be painful. Occasionally there is swelling and redness. Besides the involvement of the laryngeal cartilages, the concha of the ear and the cartilages of the ribs may be the site of inflammation. Of our cases, two showed pain and tenderness over the costo-sternal junctions, and this did not progress to suppuration.

These two complications, then, tenosynovitis and perichondritis, may suggest the diagnosis of gonococcal infection, especially if they are accompanied by arthritis.

Another complication of gonorrhea is endocarditis, and when it occurs in association with arthritis the etiologic diagnosis may give rise to some confusion and difficulty. The sudden appearance of cardiac murmur due to ulceration of the valves may, however, give important aid in the diagnosis. This was so in case 5.

CASE V

Case with Gonococcal Polyarthritis, Tenosynovitis and Ulcerative Endocarditis without Obvious Portal of Entry

A negress, 28 years of age, was admitted to the hospital with the complaint of pains in the joints. Six days before entry she developed pain in the metacarpal-phalangeal articulation of the left thumb. Two days later both shoulders, the right elbow, the left wrist and the left knee were also painful, tender and warm. All joints had subsided before entry except the left wrist and the metacarpal-phalangeal articulation of the left thumb. There had been profuse recurrent sweating and general sensation of fever for four days.

The patient denied the symptoms characteristic of an acute genito-urinary infection by the gonococcus. There had been moderately severe dysmenorrhea and profuse yellow vaginal discharge for one year. The menstrual period had begun eight days before entry and profuse bleeding continued.

On admission the temperature was 102° F, the pulse rate was 26 per minute. The patient was a well developed and well nourished negress who appeared moderately ill. There were small lymph nodes palpable in the anterior cervical and inguinal regions. The tongue was coated. The tonsils and pharynx were somewhat injected. The examination of the chest and lungs revealed no abnormality. The heart was of normal size to percussion, the first sound at the apex was accentuated, no murmurs were detected. The systolic blood pressure was 115 mm. of Hg, and the diastolic level was 70 mm. of Hg. Examination of the abdomen revealed no abnormalities. The external genitalia were normal. Pelvic examination was not done because of vaginal bleeding. The dorsal aspect of the left wrist showed swelling, tenderness, increased heat and redness. The swelling followed the outline of the tendon sheaths. The base of the left thumb and the left thenar eminence was red, painful, tender and hot. Motion of the thumb caused considerable pain.

The patient remained in the hospital for 18 days before death. The temperature

showed daily variations between 98° F and 104.6° F. There was profuse sweating but no associated chills. The symptoms and signs referable to the joints and tendon sheaths varied little. On the second day after entry there was heard over the base of the heart a diastolic murmur which, as time passed by, became louder, rougher and was eventually radiated over the whole of the precordium. Three days before death the systolic blood pressure was 114 mm. of Hg, and the diastolic level was 44 mm. of Hg. The classical signs of aortic regurgitation were noted. There were no embolic phenomena. Uterine cervical smears revealed no gram-negative diplococci. The gonococcal complement fixation test on the blood serum was repeatedly positive. The blood Kahn, Wassermann and Hinton tests were also positive. Gonococci were grown from one of many cultures of venous blood. In spite of the administration of iron and ammonium citrate the hemoglobin remained under 60 per cent of normal. The leukocyte counts varied between 11,300 and 33,500 per cubic millimeter. The proportion of polymorphonuclear cells varied between 85 and 92 per cent.

The necropsy revealed an ulcerative endocarditis of the posterior cusp of the aortic valve, gonococci were demonstrated on culture of the vegetation. The fallopian tubes and ovaries were normal. The cervix was not examined.

In this patient, arthritis was the condition that caused the greatest discomfort at the onset and the ulceration of the aortic valves developed while she was under observation. There were no local signs of gonorrhea and even at autopsy no evidence of an active gonococcal infection of the genito-urinary tract was found. That this is not an uncommon state of affairs is amply shown in Thayer's⁶ cases in which the portal of entry could be demonstrated in only about one-half the fatal cases. The appearance of an ulcerative endocarditis during the course of an acute arthritis, especially if there is a tenosynovitis, should always lead one to suspect a gonococcal infection.

From these four cases, it is evident that a number of clinical features aside from arthritis, may appear during the course of the gonococcal infection. In obscure cases of arthritis they may be of considerable assistance in establishing the diagnosis if they are present.

In addition to the clinical features of the disease, the bacteriologic, cytologic and serologic examinations of the blood and synovial fluid are of the highest importance in establishing a diagnosis.

SUMMARY AND CONCLUSIONS

- 1 The clinical features of 69 cases of gonococcal arthritis are presented.

- 2 Gonococcal arthritis is much more often polyarticular than monoarticular.

- 3 The presence of an associated metastatic conjunctivitis, iritis, perichondritis, tenosynovitis and ulcerative endocarditis are often suggestive and helpful features in the diagnosis of gonococcal arthritis. Illustrative cases are presented to emphasize these points.

- 4 The cytologic, bacteriologic and serologic examinations of the synovial fluid were of the greatest value in diagnosis, and of less value in prognosis.

A NEW TREATMENT FOR VARIOUS KINDS OF COMA *

By DR RICHARD BAUER, *Professor of Internal Medicine,
University of Vienna*

OUR knowledge of the chemical-physiological mechanism of death is incomplete. This mechanism is perhaps best understood in certain intoxications, in which the oxygen supply is disturbed, or in certain diseases of the brain, in which large areas of brain tissue are destroyed. We are little informed, however, as to the mechanism of death in the infectious diseases. We do not understand to what final factors death may be attributed in instances of cardiac diseases, carcinoma or tuberculosis. Quite unclear also remains at times the cause of death following various operative procedures.

Also the peculiar conditions of stupor and coma, frequently anteceding death, are as yet unexplained.

More knowledge of the chemical-physiological mechanism has been accumulated in instances of the diabetic, uremic, hepatic and pancreatic coma, and also in diseases of the suprarenals and hypophysis, although much awaits further explanation.

Thus, it is not surprising that the so-called hypochloremic coma was not known until 1927. We know now that hypochloremic coma is likely to arise, whenever dehydration and hypochloremia occur, followed by uremia and coma without any significant disturbance in kidney function. This occurs especially after a diet which is poor in NaCl, or follows a loss of body fluid in instances of diarrhea, vomiting, profuse perspiration, tapping, etc. At the same time an alkalosis is present, which explains the similarity of symptoms of alkali-intoxication and of hypochloremic coma.

Not long ago I¹ reported the case of a patient whose only clinical symptom was anuria. There was no renal pathology. After two days of relative well-being the patient went into coma and died. Autopsy revealed an extensive pancreatic necrosis but no significant kidney damage. The serum contained 400 mg per cent of urea. This case represented a non-nephritic uremia apparently due to the anuria. Ambard recently expressed the belief that such an anuric uremia is not due to urinary retention, but occurs on the basis of a secondary protein breakdown.

In another case of pancreatic tumor the outstanding clinical symptom was persistent vomiting. The urine was free from NaCl and the blood showed considerable hypochloremia and a large amount of urea. The patient improved temporarily after NaCl administration. Two weeks later he developed coma and died.² The autopsy revealed a carcinoma of the body of the pancreas which had compressed the stomach and duodenum. As hypochloremia has been produced experimentally in pancreatic damage, the

* Read at the Chicago meeting of the American College of Physicians, April 18, 1934.

hypochloremia in this case may be explained not only on the basis of the persistent vomiting, but also on the basis of the pancreatic disease. In both of these cases death occurred with the symptoms of non-nephritic uremia.

May I proceed now to the results of my experience as to the treatment of such patients. An apparently healthy man suddenly took sick with severe dyspnea, which soon was followed by cyanosis, myocardial failure and enormous liver enlargement. The diagnosis at this time was adhesive pericarditis. The patient improved slightly under cardiac therapy but soon developed signs of uremia and slipped into coma. The blood contained 400 mg per cent of urea. Because of previous good results which I have obtained with liver extract in patients with edema of the liver, this patient was given an intramuscular injection of Hepatrat (3 c c) (Nordmark Werke, Hamburg). Shortly thereafter the patient recovered from the coma and inquired about his condition with free sensorium. Although the uremia disappeared entirely, the patient finally died of myocardial failure.

Similar good results were obtained with liver extract administration in another patient aged 86, suffering from myocarditis, suburemia due to prostatic hypertrophy and myocardial failure. This patient lived for a year, during which time he felt well. Good results were also obtained in a case of septicemia.

E Hammerschlag³ reported similar good results in the following cases:

- 1 Liver disease of doubtful etiology, jaundice, diabetes, increased non-protein nitrogen, coma. Cured by liver extract injection.
- 2 Gastric tetany in duodenal ulcer, hypochloremia and uremia, improvement following NaCl administration. In spite of operation, uremia continued, it later subsided as the result of injection with liver extract. The patient died later as a result of peritonitis.
- 3 Acute gastro-enteritis, coma, no uremia, no hypochloremia. Cured with injection of liver extract.
- 4 Gastro-enteritis, jaundice, stupor. Uremia with normal chloremia. Septicemia with enterococcus. Cured with liver extract injection.
- 5 Empyema of the gall-bladder, coma. Operation could not be performed. Coma cleared up after liver extract injection.

Similar good results were obtained in instances of hyperemesis gravidarum, postoperative coma, extensive burns, etc.

It may be mentioned here that Robineau recently demonstrated that after operations there is an increase in urea and non-protein nitrogen in the blood. Considering the frequent presence of protein-resorption, the diminution of the intra-abdominal pressure which normally is directed toward the liver, and the circulatory failure, it becomes apparent that the danger of the occurrence of non-nephritic uremia in these cases is considerable.

The curative effect of liver extract injections in these cases is difficult to explain. I believe that the severe symptoms are due to a secondary breakdown of protein. This has been made probable by the studies of Ambard in cases of anuria. While in the hypochloremic conditions a protein breakdown frequently has been assumed, this seems to be certain only in toxic-septic conditions. In liver and pancreatic diseases the nitrogen metabolism is most likely disturbed. In hyperemesis, eclampsia and in post-operative conditions an increased protein breakdown is assumed. With the assumption in mind that the liver extract contains some liver specific constituents, perhaps hormones, the question arises whether an improved liver function might successfully counteract the consequences of an increased breakdown of proteins.

This question, I think, is to be answered in the affirmative. The action of the liver is diuretic and detoxicating. The liver converts NH_3 into urea, which in uremia may be excreted by way of the bile. The liver certainly also plays some part in the interrelationship with other glands.

An interesting point may be mentioned especially. During the process of breakdown of proteins there also occurs a breakdown of the nucleoproteids, which are converted in the liver into the nucleotids. Nucleotids are composed of either carbohydrate, phosphoric acid, guanine, adenine, or of carbohydrate, phosphoric acid and pyrimidines. While guanine and adenine are deaminized in the liver and oxidized to uric acid, the pyrimidines presumably are broken down in the liver into hydantoin and finally into carbon dioxide, urea and pyruvic acid. The pyrimidines contain the same nucleus as depressants such as veronal, amytal and luminal, while hydantoin contains the nucleus of nirvanol.

During the process of increased breakdown of proteins, the organism becomes overflowed with these substances. Although the liver is capable of converting the ammonia of the amino acids into urea, this organ is unable to get rid of the numerous products of the broken down proteins. Whenever the pyrimidine nucleus cannot be broken down any further, "auto-narcosis" of the organism is likely to occur. The sudden dramatic improvement due to liver extract injection, as seen by Hammerschlag and myself, may well be explained by the assumption that the organism apparently is liberated from the broken down protein products, which have a narcotizing effect, as the result of the increased fermentative liver action. Ruskin considers possible such "auto-narcosis" in true nephritic uremia as well as in instances of the damaging action of the broken down nuclein in cases of nephrosis. According to Baudisch and Pfalz the pyrimidine breakdown is hastened by administration of iron. Ruskin, therefore, recommends in nephrosis the administration of iron, and stomach and liver substance in order to increase the hemoglobin content of the blood and to obtain an increased iron action. Liver administration in nephrosis, as recommended by Grossman years ago, has not proved successful, nor has liver extract injection real effect in true uremia. The rapid beneficial effect of

liver extract injection in non-nephritic uremia makes a fermentative, hormonal action all the more likely as most of the patients are not anemic (See Ruskin ⁴)

Quite recently sudden improvement following liver extract injection has been observed in post eclamptic coma. The comatose mother, as well as the asphyxiated comatose infant, were saved by this therapy. In view of the postoperative protein breakdown and the factors mentioned above, liver extract injections in postoperative patients are all the more to be recommended since this treatment also has been advocated in instances of post operative thrombosis.

In spite of all these reflections it may be considered possible that the substances in liver extract which counteract the tendency to coma are not formed in the liver but only stored in it, like the "anti-pernicious" principle which is formed in the stomach but found in liver tissue.

METABOLIC STIMULANTS WITH PARTICULAR REFERENCE TO SODIUM DINITROPHENOL *

By EDWARD L. BORTZ, F A C P, *Philadelphia, Pennsylvania*

INDIVIDUALS coming to the medical service of The Lankenau Hospital with cardiac, nephritic, gastrointestinal, blood and other disorders, as well as diabetes and obesity, have been studied more and more in the nutritional section of the Metabolic Clinic. It is remarkable to note how many functional disturbances clear up when patients are placed on a sensible, restricted but adequate diet with the avoidance of coffee, tea, tobacco and alcohol. The writer has been interested for several years in the relationship of body weight to the optimum functioning of patients and has tried numerous methods to cause a reduction in adiposity.

The best system of weight reduction remains that of limit of intake of food and increase in output of energy. All cases ordinarily may reduce satisfactorily on restricted caloric intake but the perplexity arises when patients have restricted their food intake to a point as low as they themselves have a desire to cooperate with the physician. It comes then to the stage in the care of these patients where the doctor in charge must often resort to drugs to obtain further weight loss. For this reason great interest is being shown in the subject of metabolic stimulants and accelerants.

THE METABOLIC COEFFICIENT

Metabolic activity is the utilization of the various nutritive elements for the maintenance of the fundamental physiological processes, the storing up of energy for later use, and the continuation of immediately vital functions. The ordinary source of materials is food, but metabolic processes continue whether or not the daily intake is adequate. If food is withheld a certain length of time, the body draws from its endogenous food supply. The nature of this supply is beyond control, fats and proteins being withdrawn in varying amounts according to their availability rather than to metabolic need.

It is of practical clinical importance to keep in mind also that there are two phases of metabolism, the anabolic or storing, or the creation of potential energy, and the catabolic or destroying, or the transformation to kinetic energy for physiological needs. The principal anabolic stimulant is insulin, which enables the body to withdraw sugar from the blood and store it in the liver and muscles, epinephrine plays an important part in the catabolic function by bringing about an immediate release of energy in the form of glycogen from the liver and muscles.

The metabolic fire, that is the vital force acting in the body, is subject to an infinite number of regulating mechanisms in the form of pro-enzymes,

* Read at the Chicago meeting of the American College of Physicians, April 17, 1934

enzymes and anti-enzymes acting at various points in the process of chemical change. This system of enzyme control is responsible for the variation in metabolic coefficient, that is, in the degree of metabolic intensity which characterizes different species, different individuals within a species and the same individual at different times.

All physicians have had a considerable experience with the use of thyroid extract and are familiar with its action, more recently, this metabolic stimulant is falling into disuse, except on rare occasions where its assistance is required because of some glandular deficiency. Extracts of other endocrine glands, especially the gonads and pituitary, have been tried with more or less favorable results. The writer has been successful in moderate degree with the use of whole ovary in addition to diet, having obtained in some patients a loss of as much as 75 pounds.

As is well known, the hormones interact with each other, with the brain centers and the autonomic nervous system. They control to a large degree organic function and the body chemistry, so the increased oxidation following their use results from stimulation of several other physiological processes. It is the writer's impression that a distinction should be made between such agents and those which have the power *directly* to increase or decrease the rate of combustion. There is a definite class of chemical compounds which have this power, the best known of which are methylthionine chloride (methylene blue) and the dinitro compounds, on the one hand, and the cyanides on the other.

There is assuredly a difference between the condition of a subject whose metabolism has been stimulated by improving the quality of the blood, for instance, and one whose cellular combustion has been accelerated by the action of a chemical compound such as methylene blue. Theoretically, the variation in the metabolic coefficient caused by these chemicals may be assumed to be due to their effect on the sulfhydryl-disulfide system, which is explained by Bory¹ as follows:

The five elements, nitrogen, carbon, hydrogen, oxygen and sulfur together constitute the foundation of the living edifice. Nitrogen and carbon are passive energy-potentials^{*} and remain inert until they are destroyed by the activity of the two opposed elements, hydrogen and oxygen. The rôle of sulfur in this process is to control, through its easily reversible reducing-oxidizing property, both hydrogen and oxygen to insure that neither will exceed the proper limit of activity. Sulfur, drawn principally from the amino acid cystine, combines with hydrogen in the tissues forming -SH, the -SH, or sulfhydryl group, is readily oxidized, giving place to the disulfide group (S-S). The disulfide group is then reduced and the process repeated. The tissues producing the most hydrogen sulfide (H_2S) consume the most oxygen, and their carbon-nitrogen fund is destroyed in the combustion with the release of heat and energy.

Moreover, it is thought that in living tissues there is an enzyme or catalyzing substance which initiates, or accelerates, the hydrogenizing of

sulfur, thereby starting combustion when an increased amount of heat or energy is the immediate need of the organism. This happens naturally during physical exercise, when the body is exposed to a low external temperature and after the ingestion of food (specific dynamic action). Probably there is another substance, an anti-enzyme perhaps, which inhibits sulfur reduction and in this way slows or stops oxidation. Also, since the reversibility of the sulphydril-disulfide system is known to be extremely sensitive to the pH of the tissues, it may be that the temporary acidosis caused by a poorly ventilated room directly slows the process of reduction and oxidation of sulfur.

It is not difficult to believe that the various metabolic accelerants which do not appear to disturb organic and nervous function while increasing the basal metabolism from 25 to 30 per cent have this catalyzing effect on the sulfur reducing mechanism and set in motion the whole train of events in the production of heat and energy, of an intensity commensurate with the dosage. With overdosage, the heat is generated faster than the heat regulating center is able to dissipate, there is a progressive rise in body temperature up to 115° Fahrenheit, and death occurs from heat rigor.

In accordance with this conception, a classification might be made as follows

Metabolic stimulants—exciting or rousing the vital functions to activity

Metabolic depressants—lowering functional activity

Metabolic accelerants—increasing oxidation } without any appreciable effect on or-
Metabolic retardants—decreasing oxidation } ganic or nervous function

The hormones, therefore, whether secreted within the body or administered artificially, the vitamins, the various "blood builders," drugs causing respiratory and circulatory stimulation, and perhaps even those promoting diuresis, should all be regarded as metabolic stimulants. Morphine, on the other hand, might be classified as a metabolic depressant acting through the nerve centers. The clinical condition of acidosis, of varied origin, acts as a metabolic depressant. It is difficult to determine the status of a drug such as quinine, which is said to hinder the action of the oxidizing ferments of both the blood and tissues, since the exact rôle of these ferments is not known.

SODIUM DINITROPHENOL 2-4

The most recently discovered metabolic accelerants are the dinitro compounds

Dinitronaphthol

Dinitrocresol

Dinitrophenol

The last two of these have already been commercialized and placed at the physician's disposal. Dinitrocresol has been studied in England by Dr. E. C. Dodds and his co-workers^{2, 3} and is available for clinical use under the

trade name of "Dekrysil" Of particular interest to the clinicians of this country is dinitrophenol, the compound which has been so extensively studied by the investigators at Stanford University and is now being widely used in the treatment of obesity in the form of its sodium salt

The history of the discovery and adaptation of the drug for clinical trial is so readily available in the current literature that it is unnecessary to repeat it here Suffice it to say it has been proved that this chemical can increase metabolism to a high level without causing damage to vital organs and functions The fundamental physiological phenomenon occurring when dinitrophenol enters the body is an extensive increase of the combustion which is neither directly nor indirectly the result of a stimulation of the nervous system There is no relation to cardiac action or to increase in muscular work The action is generalized and appears not to involve any special organ or body system Extensive investigations have proved that the *usual* energy materials are burned independent of the type of diet Nitrogen excretion remains normal and the fats are completely burned without giving rise to acidosis

CLINICAL EXPERIMENTS

For the purpose of determining the efficacy of sodium dinitrophenol as an accelerant of catabolism, clinical observations have been made in the Metabolic Clinic of the Lankenau Hospital on a series of patients, 35 of which serve as the basis for the present discussion The series itself will be reported more fully at a later date The majority of these patients were women and were selected more or less at random, making certain to keep in mind the published contraindications to the use of the drug The patients studied had all previously been on reduction diets and had reduced as far as they themselves believed they could possibly go by dietary methods In addition, about 35 per cent had taken thyroid extract or ovarian substance with variable results

Each patient was given capsules containing 100 milligrams of the purified sodium dinitrophenol to be taken morning and evening after meals After taking two capsules a day for a week, making certain that no ill effects were present, the dosage was increased to three capsules a day, one after each meal From time to time basal metabolic readings, and blood, urine and other metabolic studies were made

It is explained to the patients that the principal effect of the medication will be a sensation of warmth, perspiration and a loss of body weight In the majority of cases the temperature did not rise over two full degrees Fahrenheit The patients ate pretty much as they pleased It is usually in the second week of therapy that patients complain of profuse perspiration and it is most important to warn them to avoid exposure to cold while perspiring After ingestion of the drug for three weeks the temperature tends to approach normal and perspiration is less pronounced although loss in

weight continues. The basal metabolism is elevated from 12 to 40 points in practically all cases. Weight loss averaged three to six pounds during the first 10 days on one to three capsules of 100 milligrams each daily. In those individuals showing a physiological response to the drug, weight loss continued at the rate of one to four pounds each week for as long a period as the medication was kept up. In about one-third of the cases an additional loss of three to five pounds took place after cessation of the therapy, following which a level was reached where no further reduction occurred.

TOXIC EFFECTS

Hyperpyrexia

Dermatitis medicamentosa

rash, pruritus, urticaria, hives

Jaundiced appearance due to staining of tissues and blood serum

Elevation of blood pressure

Pulmonary edema

Gastrointestinal reactions

General weakness, nervousness

Headache, dizziness

Exaggeration of psychoneurotic tendencies or of any pathological condition present

Toxic symptoms generally appear when the basal metabolic rate is raised above + 50%

Five of the 35 patients complained of minor symptoms such as urticaria, indigestion, nervousness, nausea and giddiness.

Two patients of the series developed what they interpreted as "pneumonia," one after taking two capsules a day for four days and the other after having been on the treatment from time to time for a few months. On physical examination of these cases at the time of the height of the fever, some râles were heard in the chest but no definite evidences of consolidation were diagnosed. There must have been at least moisture present but whether or not this was due to a respiratory infection per se, or was the effect of the drug as an irritant on the respiratory mucosa one cannot say.

One hypertensive subject developed a marked rise in both the systolic and diastolic pressure which to date it has been impossible to bring down to normal. On the other hand, a very obese male, weighing 380 pounds and with a notable endocrine dyscrasia, showed a great increase in sugar tolerance as his weight was reduced.

Another patient, who had developed a rather severe carbuncle just before the treatment was instituted showed the jaundiced appearance said to be due to staining of the blood serum and tissues with the drug.

Pain in the calf muscles was experienced in several cases.

One man on dinitrophenol twice a day for three weeks exhibited a slight urethral discharge which was non-specific in bacteriology; four years previously he had had a Neisserian infection.

Eight patients have had colds during the treatment.

Two stopped the medication because they disliked the sensation of warmth.

The most severe reaction was in a young woman, 24 years of age, weighing 160 pounds, with dysmenorrhea and evident glandular dysfunction. She was given one capsule a day for three days, two capsules a day for three days and then started on the regulation dose of three capsules a day after meals. Ten days after ingestion of the first capsule and after losing 3½ pounds in weight, she developed diarrhea, intestinal colic, generalized edema most prominent in the face and extremities, tingling and numbness of the extremities, and an urticarial rash extending from the forehead to the feet. The wheals were about the size of a half-dollar, elevated, red and radiat-

ing heat. The temperature was 102° Fahrenheit. The medication was discontinued, the patient was placed on a milk-toast diet, given calcium gluconate and a lotion for the itching. Within four to six days, the itching and rash had subsided and at the end of another week the patient was given one capsule a day with no ill effects, the dosage was gradually raised as in the first instance and five weeks after institution of the therapy, she had lost 10½ pounds, which she considered sufficient and discontinued the medication.

Most of the patients are losing weight consistently and like the treatment. Where there are no unfavorable reactions, they note an improvement in their general physical condition and have a desire for more activity. One of the concomitant effects of the drug is a general increase in well-being, a glow of the whole body, and a brightening of the mind. Since in these patients no other signs of toxicity have been noted, this is not likely a toxic effect.

DOSAGE

It may be possible that there are extremely susceptible individuals in whom even minute quantities of the drug may prove dangerous. The writer has not seen any such cases. Several fatalities and a number of untoward effects have been reported in the literature but in many cases either the dosage was too high or the dinitrophenol was not correctly administered.

To preserve the factor of safety, no patient should be given, at the onset of treatment, more than 100 milligrams a day for seven days. In the event that an idiosyncrasy is revealed, the development of serious consequences can be avoided by prompt withdrawal of the drug. If the patient exhibits no unfavorable symptoms on one capsule of 100 mg per day for seven days, it is safe to increase the dose to two capsules and then to three capsules daily, which is the accepted therapeutic dose.

In the ordinary case, not more than 100 milligrams should be given at any one time, yet in a few cases in the present series larger doses have been given, exercising great care, with no apparent detriment to the patient. The highest dosage ever used was 200 milligrams four times daily.

Certain patients seem to be resistant to the drug and where there is no weight loss on the regulation dose, if the daily dosage is pushed beyond four capsules of 100 milligrams each, toxic symptoms, principally headache, vertigo and nausea, will develop.

ACUTE INTOXICATION

The use of dinitrophenol is too new for many cases of acute intoxication to have been reported but now that it is being dispensed by druggists without prescription, such intoxications are likely to be met with at any time and a definite, well thought out plan of procedure will be of value to the doctor called in to treat the case. Profiting by the experience of others⁴⁻⁶ the writer would suggest the following measures as the most logical to resort to in handling an emergency of this kind.

- 1 Venesection (300 to 800 c c)
- 2 Intravenous injection of 100 to 300 grams of glucose in 1000 c c of physiological saline solution
- 3 Insulin 5 to 15 units, repeated every two to four hours covered by glucose
- 4 Orange juice, sugar cubes, fluids by mouth
- 5 Cooling baths
- 6 Oxygen therapy
- 7 Morphine in sufficient dosage to allay the restlessness and apprehension

CONCLUSIONS

From the author's experience it has been concluded that sodium dinitrophenol 2-4 is an accelerant of body metabolism capable of causing a notable reduction in weight. If used without regard to a planned diet, that is, a reduction diet of 700 to 1000 calories, weight loss will not be so striking although still taking place. One would get the impression that patients may be made to lose weight continually over as long a period of time as the drug is being taken and at a rate proportionate to the quantity ingested. Used with caution, this drug should prove to be a valuable adjunct in the treatment of those individuals who find it difficult or impossible to lose weight by the usual established method.

As might be expected dinitrophenol acts most satisfactorily in patients with the exogenous type of obesity. Individuals with pituitary or gonadal glandular deficiency often tolerate the drug badly or not at all. In two patients with mild myxedema, a heightening of thyroid activity approaching the thyreotoxic state has been noted after three weeks' medication, in this event immediate cessation of dinitrophenol therapy is imperative. This drug is not a substitute for thyroid extract.

It is exceedingly unfortunate for the laity that no law now exists to prevent the indiscriminate dispensing of powerful drugs such as the dinitro compounds. The therapeutic dose of 300 milligrams daily administered in three doses of 100 milligrams each is but one-tenth to one-third of that dispensed freely over drug counters today. We have knowledge of cases that have taken 15 to 30 times this quantity though not under the care of a private physician. One wonders how high the toll of deaths is going to mount when the beauty parlors and physical culture emporiums begin to pass it around. For the protection of the public, which is one of the principal responsibilities of the medical profession, and at the suggestion of an eminent jurist, the writer earnestly recommends that sodium dinitrophenol and allied chemical compounds be included in the list of dangerous drugs, the control of the use of which is governed by the Federal Food and Drug Law. These chemicals are not yet ready for general distribution through the medical profession of the country and it is unfortunate that druggists are insensitive to the fact.

That sodium dinitrophenol, dinitrocresol and other metabolic accelerants are of real value for the reduction of body weight in certain selected patients

who find it impossible to reduce by limitation of diet, is no doubt true. The writer, however, does not unreservedly recommend their use at this time and desires to stress that the safest and best way to lose weight is under the supervision of the doctor who will prescribe a diet adequate in all essential nutritive elements but limited in caloric value to such an extent that the patient's daily physiological needs will force him to draw on the fat reservoirs of the body. When the medical profession arouses itself to its obligation of service to those individuals requiring or wanting to reduce their body weight, and outlines a sensible regime to this end, the diet sanatoriums and quacks and charlatans will have a diminishing financial return and the general health of the community will be greatly benefited.

The author desires to express his sincere thanks for the helpful and critical cooperation and suggestions of his colleagues, Dr. Anthony Sindoni, Jr. and Miss Ethel May Hobson.

BLOOD CHOLESTEROL AND CREATINE EXCRETION IN THE URINE AS AIDS TO DIAGNOSIS AND TREATMENT OF HYPOTHYROIDISM

By JULIUS H. HESS, F A C P, *Chicago, Illinois*

THE clinical symptoms of diminished thyroid activity in their classical form, during infancy and childhood, are too well known to bear repetition. One of the most important problems in the care and treatment of congenital or acquired hypothyroidism during childhood is early recognition. It is reasonable to assume that the longer treatment is delayed, the less opportunity there is of attaining the most desirable therapeutic result. Until recent years, physical signs, clinical symptoms, and basal metabolism determinations were the most important methods of establishing the diagnosis of hypothyroidism.

In infants and children, the characteristic physical appearance, subnormal temperature, retardation of growth, and other well known symptoms of hypothyroidism present a striking clinical picture. The classical symptoms and physical appearance are not, however, always present in early infancy and the clinically questionable cases in older children make it desirable to have additional aids in diagnosis.

Basal metabolism determinations have been of invaluable aid in assessing thyroid activity in older children and in adults. The limitation of basal metabolism determinations in children below the age of eight is, however, apparent when we consider that in most cases this can be accurately carried out only by direct calorimetry (measuring heat production directly in a closed chamber). Such an apparatus is not ordinarily available to the physician. Even in older children, the lack of cooperation due to mental retardation, excitement, or nervousness often renders the test unsatisfactory in obtaining reliable information.

For the past year we have been interested in the level of cholesterol in the blood and the excretion of creatine in the urine, as possible aids in early diagnosis and in gauging treatment with thyroid medication in the thyroid-deficient child.

BLOOD CHOLESTEROL

The work done at the Lahey Clinic with hypothyroidism and hyperthyroidism in adults indicated that the level of blood cholesterol might serve a useful purpose as a further laboratory check on the severity of hypothyroidism or hyperthyroidism, since the basal metabolic rate did not always give a true picture, and the clinical impression was difficult to define. A striking relationship between hypothyroidism, blood cholesterol, basal metabolic rate, and clinical improvement was observed. They concluded from

* Read at the Chicago meeting of the American College of Physicians, April 19, 1934

their study that cholesterol reflected better the severity of hypothyroidism and the true clinical condition than does the basal metabolic rate

We undertook an investigation for the purpose of determining the blood cholesterol relationship in thyroid-deficient children, having in mind the possibility of its use as a corroborating test in controlling thyroid dosage and maintaining metabolism at a normal level. In order to establish the average blood cholesterol for the group of hypothyroid children studied, the values of this lipid were determined in 25 children (table 1) ranging in age from two months to 11 years. In this group of patients, no derangement of cholesterol metabolism was present. The average level of blood cholesterol was 190 mg per 100 c c of blood. This determination is consistent with the values found by other workers in this field as cited in the literature on blood cholesterol in infants and in older children.

TABLE I

| Sex | Age | Cholesterol | Diagnosis |
|------|--------|-------------|--------------------------|
| 1 M | 2 mos | 200 | Normal child |
| 2 F | 2½ mos | 200 | Normal child |
| 3 F | 3 mos | 185 | Pyloric spasm |
| 4 F | 5 mos | 208 | Normal child |
| 5 M | 9 mos | 185 | Upper resp infection |
| 6 M | 11 mos | 185 | Cleft palate |
| 7 F | 13 mos | 208 | Pyelitis |
| 8 M | 13 mos | 217 | Achondroplastic dwarf |

Originally eight boys and four girls were studied and the blood cholesterol values in these children when not under treatment ranged from 277 to 782. The presence of hypercholesteremia was definitely established in these twelve patients, and this excess of cholesterol in the blood was definitely reduced upon the administration of thyroid extract. Likewise, a marked clinical improvement followed.

Since the first communication, we have added to our list 12 more thyroid-deficient children, making a total of 24. In all of these hypercholesteremia was present when thyroid extract was not taken. In a number of the above, basal metabolism was impossible of performance and blood cholesterol was used as the guide in regulating therapy and following the clinical course.

I shall now present three patients in whom blood cholesterol was put to clinical use.

CASE REPORTS

Case 1 G M, a boy, aged $9\frac{1}{2}$ years had been under treatment previous to the undertaking of this study. It was not quite clear that he was a cretin, but after two months without treatment he presented typical characteristics.

On April 12, 1932 (up to which time he had been receiving from 2 to 3 grains (0.13 to 0.2 gm) of thyroid a day), it was decided to stop thyroid. At this time his cholesterol was 156, the basal metabolic rate was plus 47, the pulse 94, and the weight $58\frac{3}{4}$ pounds (26.6 kg). In the two months that thyroid was withheld, his weight rose to $65\frac{1}{8}$ pounds (29.5 kg), a gain of $6\frac{3}{8}$ pounds. The cholesterol rose to 454, a change of 298 milligrams, the basal metabolic rate fell 58 points, and the pulse fell 40 points. When thyroid (2 grains daily) was started, the cholesterol fell to 172, a change of 282 milligrams, the basal metabolic rate rose 48 points, the pulse rose 42 points, and he lost $5\frac{7}{8}$ pounds. After the two months without medication, the hair had grown coarse and the abdomen large, and myxedema had appeared.

Case 2 A B, a boy aged 13, entered the hospital with a blood cholesterol of 454 and a basal metabolic rate of minus 41. The bony development of the wrist was that of a five year old child. In 15 days on approximately 1 grain (0.065 gm) of thyroid extract daily, the cholesterol fell to 200 and the basal metabolic rate rose to 0.

At this time we were interested in the possibility of influencing cretins by other means, as for example, by insulin, as suggested by Chamberlain, since insulin will diminish the hypercholesteremia in diabetes. The pancreatic hormone was used for 43 days, during which period thyroid was stopped. The cholesterol rose from 200 to 454 and the basal metabolic rate fell from 0 to minus 35. When thyroid was again instituted, the cholesterol fell to 208, a fall of 246 points, and the basal metabolic rate gradually rose 71 points. In the course of a little over two weeks, the thyroid was rapidly increased from 1 to 8 grains (0.065 to 0.5 gm) and the patient was kept on this large dose for a short period, following which improvement in his appearance and mental reaction took place.

Case 3 D B, a girl 15 months old, is the youngest cretin in our group. She had a normal birth and was breast fed for three months. At three months, when breast feeding was stopped, the mother observed weakness of the child's voice, dryness of the skin and hair, and laziness in food taking and in movements. The infant was suspected of being a cretin. Basal metabolism was impossible since no enclosed respiratory chamber was available. Her initial cholesterol reading was 416 and upon thyroid therapy, starting with $\frac{1}{2}$ grain and increasing to $1\frac{1}{2}$ grains, marked clinical improvement was noted. The blood cholesterol fell gradually to 333, 312, 227 and the last few readings have been normal, 208, 179, and 147.

In this study the total blood cholesterol only was estimated. Cholesterol appears in the blood in the free state and as cholesterol ester, the relative proportions being 20 to 50 per cent of free cholesterol and 50 to 80 per cent of cholesterol ester. Schwartz and Topper suggest that the examination of the various fractions may be of further interest. They found in children with hypothyroidism not only an increase in the total blood cholesterol, but at times a disturbance of the ratio of ester to free cholesterol, of such a nature that the relative proportion is reversed, and they showed that this ratio may become normal after intensive treatment with thyroid extract. It is, therefore, possible that the determination of the ratio of free cholesterol to the ester may give us further valuable information in the diagnosis and treatment of hypothyroidism.

CREATINE EXCRETION

The discovery of the metabolic functions of creatine in muscle metabolism has attracted considerable clinical interest to the study and treatment of disorders of the muscular system, particularly in pseudohypertrophic muscular dystrophy and in myasthenia gravis. Harris and Brand¹ have reviewed this subject well.

It seems likely that creatinuria in the human is related to defective creatine storage in muscle or to abnormally high creatine synthesis. Creatinuria occurs in all types of muscular dystrophy and in states of increased endogenous protein catabolism, as in fever and in certain cases of hyperthyroidism.

Normally creatine is not found in the urine of the male adult, but small amounts of creatine are excreted periodically in the urine of normal women. In infants and children, however, creatinuria is physiological in both sexes until about the age of puberty.

From the observations in current medical literature, it appeared that the relationship of the creatine metabolism to thyroid activity in children might be of clinical interest.

Extensive creatine and creatinine excretion studies were carried out on 34 children, including normals and children with various disease conditions. Detailed observations are reported at this time on two cases of hypothyroidism in children. Twenty-four hour urine specimens were collected on two female children with hypothyroidism, one (D. J., age 6 years) for 53 consecutive days, and another (V. K., age 11) for 36 consecutive days. The preformed creatine was determined by the Folin colorimetric method and the total creatinine by the Folin-Benedict method in duplicate. The patients were on a general hospital diet containing meat once a day and approximately a quart of milk a day. Rectal temperatures were taken three times a day.

These two children showed an absence of the physiological creatinuria of childhood when not receiving thyroid therapy or creatine by mouth. The absence of creatine from the urine was not due to a low protein intake as the diet described was not creatine free and contained an adequate amount of protein. In the case of the older subject (V. K.) the experimental period was started while she was still on thyroid extract. This patient showed a gradual decrease in urinary creatine as the amount of thyroid extract administered was reduced. She continued to excrete creatine for three days after thyroid therapy was discontinued.

The hypothyroid children studied have shown a definite change in creatine metabolism. This is characterized by a diminution or complete absence of the physiological creatinuria usually found in children up until the age of puberty. Thyroid feeding restores the hypothyroid child to the condition of creatinuria characteristic of the normal child. The creatinuria is seen to be a very delicate index of the effect of ingested thyroid inasmuch as it occurs even before any definite change is noted in the basal metabolism.

and blood cholesterol It is not possible to state how the thyroid hormone affects the creatine metabolism, but it is obvious that directly or indirectly it exerts a profound and determining influence upon the character of creatine metabolism A probable explanation of the diminished creatine excretion is that it may be due to a low endogenous metabolism incident to hypothyroidism

The comparison of the changes in creatine excretion with other criteria of the efficacy of treatment in hypothyroidism is interesting It will be noted from the charts that following thyroid therapy a change in creatine excretion takes place long before there is a significant change in the basal metabolic rate, blood cholesterol, or body weight From these observations, it seems apparent that measurement of the urinary creatine is a delicate index of the effect of thyroid administration In view of the greater ease, simplicity, and reliability of creatine analysis than of the basal metabolic rate in children, it seems that this measurement may serve as a useful clinical aid in controlling thyroid medication

SUMMARY

The value of further aids in the diagnosis and treatment of thyroid-deficient children is discussed The rôle that estimation of blood cholesterol and creatine excretion plays in the urine is indicated

Blood Cholesterol The blood cholesterol is high in children with untreated hypothyroidism, and is reduced by thyroid medication

The level of blood cholesterol may be used as a guide to the efficacy of thyroid therapy

Creatine Excretion in the Urine The metabolism of creatine appears to be definitely influenced by thyroid activity during childhood

During the period from infancy until about puberty, creatinuria is physiological Hypofunction of the thyroid causes a decrease or complete cessation of creatine excretion which can be restored to normal values after the administration of thyroid extract This is accompanied by a corresponding change in the clinical condition of the patient

The creatinuria is a very delicate index of the effect of ingested thyroid inasmuch as it occurs before any definite change is noted in the basal metabolism and blood cholesterol

From a comparison with other diagnostic criteria of hypothyroidism in children, the change in creatine metabolism appears to be an important finding which may be useful in diagnosis and in the control of therapy

SEPTICEMIA *

By JOHN A. KOLMER, M D , F A C P , *Philadelphia, Pennsylvania*

Definition While the condition septicemia is well understood clinically yet it is hard to define in a clear and concise manner, hence many definitions have been offered. It is characterized by pronounced signs and symptoms of infection due largely to the presence of pathogenic organisms and their products in the blood and is usually associated with infection of the fixed tissues. In my opinion it is best defined as *an infection of the blood* because this phase greatly predominates in the clinical manifestations.

Emphasis is placed upon *infection* of the blood with all it implies as differentiated from invasion of this tissue. That is to say, the blood may be temporarily invaded by pathogenic organisms without showing any signs of infection, for this state the term *bacteremia* may be used. For example, streptococci may be found at times in the blood by culture in chronic arthritis without any signs or symptoms of infection as far as the blood is concerned. Furthermore it would appear that the gonococcus may be transmitted to the joints without clinical evidences of its temporary presence in the blood and it may be that the tubercle bacillus and other organisms may be found in the blood by culture without evidences of infection. All of this indicates that the mere presence of pathogenic organisms in the blood per se does not necessarily produce signs and symptoms of infection or constitute septicemia.

But when the immunological resistance of the blood is broken down by unusual numbers or virulence of the organisms or by other factors permitting the organisms to multiply in the blood along with the presence of toxins, aggressins or other bacterial agents, signs and symptoms of this infection of the blood are present and along with primary or secondary infection of the fixed tissues constitute the symptom complex or syndrome designated as septicemia.

In many instances this infection of the blood results in the production of abscesses or metastatic foci in other organs and tissues and especially in infections with the pyogenic cocci. When this happens the state is sometimes designated as *pyemia* or *septicopyemia* but it would appear that these terms are superfluous and unnecessary.

Since most instances of septicemia are secondary to infection of a fixed tissue some prefer to speak of the state as sepsis but this is hardly justified since it would appear that septicemia may sometimes occur without a detectable primary focus of infection or without pronounced evidences of infection.

* Trimble lecture before the Medical and Surgical Faculty of Maryland, April 24, 1934.

at the probable portal of entry of the organism, this constitutes the so-called *cryptogenic septicemia* first described by Leube about 55 years ago

Immunological Considerations Our information on the mechanism of the natural and acquired defenses of the blood against infection is very incomplete but it would appear that whatever they may be they are inadequate, break down or fail to sufficiently develop in septicemia. Hence a very important phase of treatment consists in supporting, supplying or bolstering immunological resistance whenever possible and this sometimes requires the physician or surgeon to secure the cooperation of the expert bacteriologist and immunologist. To know what to do, when to do it and to meet the changing clinical conditions without the error of attempting to do too much requires unusual experience and common sense since all cases must be strictly individualized with hardly any two exactly alike, but more of this later

Undoubtedly the blood is able to clear itself of small numbers of organisms by phagocytosis on the part of fixed cells of the reticulo-endothelial system in the liver, spleen, bone-marrow, lymph glands, etc. Indeed this phagocytosis would appear to be a very important factor in natural defense against septicemia and also in the mechanism of recovery, but apparently it requires the presence in the body fluids of adequate amounts of such antibodies as agglutinins and opsonins. In septicemia therefore the phagocytosis of organisms in the blood by reticulo-endothelium may fail or prove inadequate, not so much because the cells are "blocked," but because they are sickened by toxins or because there is insufficient production of these humoral antibodies, especially opsonins, believed to be so important in phagocytosis. These may be supplied to some extent by the timely administration of some of the immune sera in proper dosage or by the transfusion of blood from a normal or immunized donor

Furthermore the blood naturally contains variable amounts of complement which appears to bear an important relationship to natural and acquired resistance against septicemia. Unfortunately its nature, the mechanism of its action and a knowledge of ways and means for causing its increase are but imperfectly understood. In septicemia it is usually decreased and this is an additional important reason for the transfusion of blood in treatment as a means of replenishment and increasing resistance

In addition the blood naturally contains small and variable amounts of bactericidal antibody for most pathogenic organisms which may or may not produce lysis and may or may not require the presence of complement for bactericidal activity. For the want of a better term this substance is frequently spoken of as "protective antibody" and has been particularly identified with pneumococcus immunity and anti-pneumococcus serum. Unfortunately its source and the mechanism of its activity are likewise imperfectly known but it would appear to be a product of leukocytes and the cells of the reticulo-endothelial system. Its presence in whole blood or serum may be demonstrated in the test tube by the Cohen-Heist or other methods but better

in the living animal, in septicemia it appears to be exhausted. The transfusion of blood from a normal or immunized donor may furnish small amounts of this kind of antibody but larger amounts may be supplied in some of the antipneumococcus, antimeningococcus and antistreptococcus sera available for prophylactic and curative purposes.

Finally the blood may contain various natural antitoxins and it is a curious fact, to be referred to shortly in more detail, that septicemia rarely occurs in infection with diphtheria, tetanus and the bacilli of the anaerobic gangrene group which owe most of their pathogenicity to the soluble or exogenous toxins. It may be that the antitoxic properties of the blood afford a large measure of protection but neutralization of toxins by transfusion of blood and the administration of immune sera exerts an important influence in the treatment of several of the septicemias and especially those caused by various types of hemolytic streptococci, the pneumococci and meningococci.

It is apparent therefore that the natural or acquired immunological principles of the blood and the fixed cells of the reticulo-endothelial system play a very important part in resistance to and recovery from septicemia, and that treatment of the state with appropriate immunological and supportive measures ranks next in importance to the carrying out, when possible, of surgical extirpation or drainage of infected areas of the fixed tissues along with attempts at disinfection with chemical agents.

Pathogenesis In the great majority of cases of septicemia infection of the blood follows by way of the lymphatics or veins from local infection of the fixed tissues and in every case the first and most important phase of treatment consists of measures favoring the localization of the infection with prompt surgical extirpation or adequate drainage whenever possible. The primary focus, however, may be small and trivial with rapid infection of the blood when the infecting organism possesses unusual virulence and aggressiveness or when natural resistance is low, and surgical treatment requires the finest of judgment and skill since hasty operative measures may break down barriers and open avenues of extension of infection. And indeed septicemia may occur with practically no evidences of local infection at the portal of entry at all as, for example, in some cases of streptococcus, meningococcus, typhoid and anthrax septicemia. In my experience these septicemias, and especially those caused by the pyogenic cocci, invariably have the gravest prognosis, not only because it is impossible to institute local drainage, but because the absence of a well defined local lesion means the absence of a depot of local antibody production.

In the majority of cases, however, local infection of the fixed tissues occurs first with the production of lymphangitis and thrombo-phlebitis followed by invasion and infection of the blood with organisms or infected thrombi as immunological resistance is gradually or suddenly broken down. The resulting symptoms and secondary pathological changes in important organs are apparently due not so much to the organisms themselves in the

blood, as to the toxic substances they directly or indirectly produce, although the organisms as such, or in bits of thrombi, may produce embolic infections and abscesses in various organs and tissues of the body. It is for this reason that an eternal watch must be maintained for secondary infections in the course of all septicemias and especially those produced by streptococci, staphylococci, gonococci and colon bacilli with surgical drainage at the earliest favorable time whenever possible.

Bacteriological Considerations While theoretically all pathogenic bacteria may produce septicemia yet some are especially likely and others especially unlikely to produce this state. The pyogenic organisms belong to the first group, especially streptococci, pneumococci, staphylococci and meningococci, and the toxin producing anaerobes to the second. The order of frequency in which the various bacteria produce septicemia is, in my experience, as follows

Hemolytic streptococci, especially *Streptococcus pyogenes*
 Non-hemolytic streptococci, especially *Streptococcus viridans*
 Pneumococci, especially in lobar pneumonia and sinusitis
 Staphylococci, especially *Staphylococcus pyogenes aureus*
Bacillus typhosus
 Meningococci
 Gonococci
Bacillus anthracis
Bacillus coli
Spirillum recurrentis
Bacillus pyocyaneus

Among the rarer septicemias are those produced by

Bacillus mucosus capsulatus
Bacillus influenzae
Bacillus proteus
Bacillus fecalis alkaligenes
Micrococcus tetragenes

Personally I have never seen septicemia due to the true diphtheria bacillus, although some cases are on record, nor to the tetanus and other bacilli of the anaerobic gangrene group although this may be due in part to the infrequency with which anaerobic methods of blood culture are employed. Doubtless *Spirocheta pallida* produces septicemia in the early stages of syphilis but it has never been cultivated from the blood although intratesticular injections of this tissue in rabbits have produced infection. Of course many of the protozoa and some of the metazoa as well occur in the blood but do not produce septicemia in the accepted meaning of the term.

In a broad and general manner there is a relationship between virulence of the organism on the one hand and septicemia on the other. That is to say, organisms possessing a high degree of invasiveness are especially likely

to produce the state. There is, however, such an important relationship between virulence on one hand and immunological resistance on the other that curious paradoxes are frequently seen. For example, the *Staphylococcus pyogenes albus* is usually regarded as an organism of low virulence leading a saprophytic existence on the skin or mucous membranes and producing but small pimples and stitch abscesses, yet it can produce one of the most dangerous septicemias with which I am familiar. *Streptococcus viridans* is so low in virulence that it is almost impossible to kill a mouse or rabbit with it and yet what more mortal disease than its ulcerative endocarditis and associated septicemia? The anthrax bacillus produces little or no toxic substance at all and yet its septicemia with remarkably few symptoms ascribable to this state gives the disease its highest mortality. The diphtheria bacillus and even more the tetanus, botulinus and other anaerobes of wound infections are terrible producers of exogenous toxins and yet how rarely do they produce septicemia. We need to know more about those bacterial poisons which are not particularly toxic of themselves but yet are capable of preventing or retarding phagocytosis and are commonly designated as aggressins and endotoxins, for an adequate understanding of the problems involved. Certainly inadequate or complete failure in phagocytosis and "walling off" at the portal of entry would appear to be an important factor in the production of septicemia.

General Etiological Considerations—Septicemia occurs at all ages and in both sexes but somewhat more frequently in the young and in the elderly, likewise more commonly among women than men on account of puerperal infections. More cases are seen during the colder months of the year because of the higher incidence of infections of the respiratory tract with special reference to sinusitis, otitis media, mastoiditis and pneumonia.

Diabetes mellitus, chronic alcoholism and chronic debilitating diseases are predisposing factors and particularly cardio-renal disease, arteriosclerosis, cirrhosis of the liver, cancer, Hodgkin's disease, etc., in relation to terminal infections with septicemia among elderly individuals. The site of primary infection or portal of entry, and the severity of the local infection at this point show great variation, in part dependent on the organism, ranging all the way from a severe puerperal endometritis to an insignificant blister on a toe from an ill-fitting shoe, and indeed, in some cases, there is no discoverable focus at all.

Hemolytic streptococci are by all odds the most frequent producers of septicemia and especially *Streptococcus pyogenes*, the usual or commoner portals of entry of these organisms being as follows:

- 1 Minute abrasions of the skin particularly in infections with the streptococcus of erysipelas
- 2 Wounds and especially trivial puncture wounds or large lacerated ones resulting in lymphangitis
- 3 Paronychia, carbuncles, bed-sores and severe burns and, as a secondary infection, the pustules of small-pox

- 4 Puerperal endometritis or sepsis where the chances for phlebitis are particularly marked
- 5 Otitis media and mastoiditis and especially with lateral sinus thrombosis
- 6 Sinusitis with special reference to the ethmoid and sphenoid cells
- 7 Tonsillar infections secondary to scarlet fever, diphtheria and septic sore throat
- 8 Osteomyelitis, especially in young persons
- 9 Infected teeth and severe gingivitis
- 10 The genito-urinary tract, especially after instrumentation, and an occasional case secondary to suppurative appendicitis, peritonitis, suppurative cholangitis, etc

Streptococcus viridans septicemia is generally associated with ulcerative endocarditis with the portal of entry most frequently in the teeth, tonsils or sinuses

Staphylococcus septicemia is fortunately much rarer but the primary foci are similar to those listed above for the streptococci with special reference to furunculosis, infected wounds, mastoiditis, osteomyelitis and puerperal endometritis

Pneumococcus and *B. friedlander* septicemia are almost always secondary to infections of the respiratory tract and particularly lobar pneumonia, sinusitis, mastoiditis and bronchiectasis

Gonococcus septicemia is fortunately rare but usually severe and fulminating with foci in the genito-urinary tract, joints or endocardium

Meningococcus septicemia may occur as an acute fulminating infection through the mucosa and lymphatics of the naso-pharynx or as a late complication of meningitis

Anthrax septicemia is nearly always secondary to primary infection of the skin (malignant pustule) or to infection of the bronchi and intestines

In *typhoid fever* there is usually an initial bacteremia but a true septicemia may occur which is always of bad prognostic import if it appears late in the disease. *Bacillus coli* septicemia is not infrequent in conjunction with streptococci or staphylococci and especially as a terminal infection in cardio-renal and other chronic debilitating diseases or from primary foci in the biliary passages and peritoneum. *B. proteus* septicemia may also arise from infections of the urinary tract while *B. pyocyaneus* septicemia most frequently occurs in infants and young children producing rapidly fatal infections arising primarily from the gastrointestinal tract

Pathological Considerations Much may be stated about the gross and microscopic tissue changes in the various septicemias but with little advantage in such a general review of the subject as this aims to present

Suffice it to state that the changes produced in any case are inflammatory or suppurative in character and generally consist of those found (1) at the site of initial infection or portal of entry, (2) secondary foci or abscesses in different organs or tissues, (3) proliferative changes in the bone-marrow,

spleen and other organs of the reticulo-endothelial system representing immunological response to the infection with blood regeneration and (4) degenerative lesions and especially cloudy swelling and fatty degeneration of the kidneys, liver, heart, brain and other organs generally ascribed to the effects of bacterial toxins

As previously stated the tissue changes at the site of initial infection may be so slight as to readily escape detection. In my experience this has been particularly true of staphylococcus septicemia. I have seen such to be nothing more than a mere abrasion of the skin with almost complete healing at the time of a rapidly fatal septicemia, and as these lines are written I have an unusually severe case following a small and healed furuncle of the skin of a finger. In meningococcus septicemia the initial lesion may be nothing more than a moderately severe naso-pharyngitis without suppuration, but as a general rule the initial lesion of most septicemias, and especially of those caused by streptococci, show pronounced suppurative changes with septic phlebitis and lymphangitis as, for example, those occurring in mastoiditis, endometritis, etc.

The secondary foci are usually embolic in character and show many curious and unexplainable distributions in the different septicemias, involving in some instances the selective affinity of organisms for certain tissues. For example, the meningococcus localizes mainly in the meninges, the gonococcus in the muscle sheaths, periosteum of the long bones, peri-articular tissues and lungs, etc. But metastatic or embolic abscesses may occur almost anywhere, in particular they are apt to affect the kidneys, lungs, pleurae, brain, spleen and endocardium. Septic or embolic bronchopneumonia and pleuritis are always to be feared, and especially so in staphylococcus and streptococcus infections.

As a general rule the spleen is enlarged, if the patient lives long enough, and is either of the soft red type showing marked hyperplasia and phagocytic activity of the reticulo-endothelial macrophages with acute congestion of the pulp, or of the grey type with a great increase of the pulp cells and large numbers of oxidase-containing myeloid elements. The bone-marrow is apt to be opaque because of a great increase of myelocytes in response to the need for granulocytes and especially for neutrophils for combatting the infection and shows evidences of erythroblastic activity stimulated by the effects of blood destruction.

Sooner or later, depending upon the severity of the infection, the toxins and the pyrexia are apt to produce hyperemia with cloudy swelling and fatty changes especially in the heart, liver, kidneys, and adrenal glands, etc. Acute meningeal congestion, or so-called toxic meningismus with hyperplasia of the arteriolar endothelium may be observed, and is responsible for the mental symptoms of headache, delirium and coma which are so likely to be present. The much dreaded paralytic ileus I believe is due to involvement of the posterior lobe of the pituitary gland. It is expressed clinically by initial diarrhea with terminal abdominal distention, nausea and vomiting.

Laboratory Aids in Diagnosis This naturally brings one to a consideration of laboratory aids in the diagnosis of septicemia, especially, since this is essentially a bacteriological problem, with reference to study of the primary focus and blood cultures

Altogether too frequently the bacteriological examination of the primary or initial foci of infection by smears and cultures is overlooked and when septicemia is finally suspected clinically much valuable information is lacking. Furthermore the chances of developing septicemia may be sometimes estimated by a knowledge of the nature of the initial infection. For example septicemia following staphylococcus mastoiditis is rare as compared with streptococcus infections with or without lateral sinus thrombosis, streptococcus endometritis is far more likely to produce septicemia than staphylococcus or other infections and in lobar pneumonia pneumococci of group IV are less likely to produce septicemia than types I, II and III although probably the group IV septicemia is even more dangerous when it does occur.

Without doubt blood cultures are of primary importance provided the proper technic is employed. Indeed septicemia is sometimes first detected by them, and the absence of classical signs and symptoms by no means excludes the possibility of a blood stream infection. As the presence of bacteria in the blood may be intermittent, two or more cultures at intervals of one or two days may be required. As a general rule microorganisms develop rapidly in blood cultures in septicemia but all should be kept under observation for at least five to ten days before reporting sterile results.

Great care is required in taking the blood to guard against contamination with staphylococci (particularly *Staphylococcus albus*) and streptococci (particularly non-hemolytic types) from the skin. Indeed it is usually advisable to repeat the culture at least once before arriving at the diagnosis of a staphylococcus septicemia in order to guard against error due to contamination.

As shown by Ottenberg, there is an advantage in taking blood for culture from a vein draining an infected area whenever this is possible. Cultures of blood from the internal jugular veins of individuals with suspected lateral sinus thrombosis in mastoiditis have, for example, sometimes yielded positive results when cultures from veins at the elbow were sterile or have shown a smaller number of bacteria. In his opinion the finding of a much greater number of bacteria in the blood from one internal jugular vein than from the other confirms the diagnosis of lateral sinus thrombosis although it is impossible from the count alone to tell on which side the thrombosis is located.

As a general rule it is a good practice to culture relatively large amounts of blood like 5 to 10 c c, and I have found glucose hormone broth with a pH of about 7.4 to 7.6 quite suitable in 100 to 200 c c amounts. By plating measured amounts of blood like 5 c c with 10 c c of glucose hormone agar, an idea of the numbers of bacteria per cubic centimeter may be obtained which is of value in estimating the gravity of the infection as well as being a guide in evaluating the results of treatment.

Unfortunately we do not have available at present a practical method for detecting or measuring the amounts of bacterial toxins which are commonly believed to be present in the blood in septicemia. It is likely that skin tests employing the serum of the patient injected intracutaneously in the lower animals and especially the rabbit, may be of aid in this connection, but mice, rats, guinea pigs, and rabbits possess such a high natural immunity to staphylococci and streptococci, that I, at least, have not been able so far to work out an acceptable method by intraperitoneal and intravenous injections of serum.

In this connection I may also mention that it is sometimes of value to *estimate the bactericidal and bacteriostatic activity of the blood* to determine at the outset the patient's chances of developing septicemia. This is done after a method of Cohen consisting in placing a small amount of pus or culture in the bottom of a sterile test tube and adding 5 c c of blood. If organisms develop in this whole coagulated blood, it may indicate a breakdown of immunologic resistance and the possibility of the development of a blood stream infection. If organisms do not develop, the reverse may be true, although I have seen septicemia develop under such conditions apparently as the result of a subsequent reduction in immunologic resistance.

Total and differential leukocyte counts are of course well known and appreciated in the diagnosis of septicemia and should be made at frequent intervals as a guide to the severity and progress of infection. A leukocytosis due largely to an absolute increase of polymorphonuclears along with a relative or absolute decrease of eosinophiles has long been accepted as the typical change.

But an estimation of the metamyelocytes or immature polymorphonuclears greatly improves the value of the differential leukocyte count in diagnosis and also as a means of estimating the severity and progress of septicemia. These cells are readily detected and divided into two types, the young and the old or banded forms. In the usual differential count they have been included in the percentage of large lymphocytes, transitionals and polymorphonuclears and their significance entirely lost. By the newer method, however, it is possible to obtain valuable information even when the percentage of polymorphonuclears is about normal.

Normally the blood contains none of the young metamyelocytes and about 4 per cent of the older ones. In acute infections both are increased and designated by Schilling as a "shift to the left." This shift may occur with but a slight and insignificant increase of the polymorphonuclears. By dividing the number of polymorphonuclears by the number of metamyelocytes, my colleagues, Boerner and Gerard, have worked out the "nuclear index" as a means of reporting. For example, there are normally about 4 metamyelocytes to 60 polymorphonuclears giving an index of 15. If the metamyelocytes increase, the index becomes lower so that an index of 10 to 15 constitutes a slight shift to the left, 5 to 10 a moderate shift, and below 5 a marked shift. *I strongly advise the adoption of this shift to the left*

and nuclear index method for routine differential leukocyte counts and reports

Furthermore, as shown by Boerner it is advisable to abolish the usual custom of reporting the different leukocytes by percentages since it is possible for the polymorphonuclears and other types to be present in a normal percentage while being actually increased. It is much better to report the actual number of each variety per cu mm of blood, the normal for older children and adults being as follows

| | |
|--------------------|--------------|
| Lymphocytes | 1000 to 3000 |
| Monocytes | 100 to 600 |
| Polymorphonuclears | 3000 to 7000 |
| Eosinophiles | 50 to 400 |
| Basophiles | 0 to 50 |

This is a more accurate and useful method since it gives the "absolute" number of the different leukocytes, as one or more types may show important changes which are not revealed by the usual percentage or "relative" system. In septicemia particular interest is attached to the polymorphonuclears and eosinophiles and I recommend the adoption of this plan even though it entails the task of forgetting percentages and training the mind to interpret the results on the basis of the total numbers of the different leukocytes per cubic millimeter of blood.

Urine examinations are of course required with special reference to specific gravity as an index of fluid intake and output, and to albumin as an index of tubular changes. The presence of leukocytes and erythrocytes may be an index of focal glomerulo-nephritis which is likely to occur, especially in streptococcus infections. Finally bacteriological examination of catheterized specimens is indicated when embolic abscesses or pyelo-nephritis are suspected.

In this connection mention may also be made of the value of *blood chemical determinations*: urea nitrogen as an index of functional capacity of the kidneys, glucose in relation to diabetes mellitus which predisposes to septicemia and always entails an especially poor prognosis, and cholesterol which when high unfavorably influences resistance probably because of associated involvement of the adrenal glands.

And finally an *examination of the cerebrospinal fluid* is of course an invaluable aid when meningitis is suspected. The usual findings, however, are typical of the acute meningeal congestion or so-called "serous meningitis" of septicemia, i.e. a perfectly clear fluid under increased pressure with normal total cell count, with no increase of protein or decrease of sugar and bacteriologically sterile.

Symptomatology and Clinical Diagnosis My records cover 282 cases of septicemia seen in hospital and consultation practice during the past 20 years, yet it is difficult and almost impossible to present a brief account of the clinical manifestations. Indeed it seems to me that no two cases caused even by the same kind of organism are ever exactly alike and this is not to be wondered at when one remembers the possible variations due to the kind and

virulence of infection on the one hand with the age and immunological resistance of infected individuals on the other, not to mention the presence or absence of predisposing factors, the site and severity of initial infection, the distribution and severity of complications and what not

Suffice it to state that some septicemias are fulminating when virulence is extremely high or resistance extremely low, with death in a few days. The majority, however, are of the ordinary acute type running a course of one to several weeks, while a few are of the subacute or chronic type in which the septicemia or positive blood cultures may persist for many weeks and even several months with surprisingly few clinical manifestations until the terminal stage is reached—with death, as always happens in *Streptococcus viridans* endocarditis, or recovery, as sometimes occurs and especially in the streptococcus septicemia following abortion, childbirth or surgical infections.

One thing is certain, namely, that on the one hand, without blood stream infection, enough toxins may be absorbed from a severe primary focus to closely mimic the clinical picture of septicemia and that, on the other, septicemia may exist with so few of the classical symptoms as to make a positive blood culture a matter of surprise. In other words an actual finding of organisms in the blood by one or more cultures is the criterion in the final analysis and reliance cannot always be placed on symptoms alone in diagnosis.

Furthermore the *incubation period* may vary apparently from a few hours or days to several weeks. Here again virulence of infection and resistance are the determining factors. For example during epidemics of meningococcus meningitis with high virulence of the organism, healthy individuals have succumbed to the septicemia within a few days of the time of infection and before the onset of meningitis, while it is not unusual for streptococcus septicemia to develop one or more weeks after mastoidectomy, not to mention the weeks that may elapse between the infection of teeth or tonsils and the development of subacute streptococcus endocarditis with septicemia. No two cases are ever exactly alike and it is impossible to assign even approximate periods of primary incubation for the different septicemias.

Probably the most constant and characteristic clinical manifestation is the high continuous or intermittent "steeple chase" type of fever reaching its low point in the morning and peak late in the afternoon or evening. A few days of this sort of thing is usually sufficient to suggest the possibility of septicemia by a mere glance at the graphic record and especially when the fever is accompanied by chills or chilliness, a rapid bounding pulse, increased respirations, flushing of the skin with profuse sweats, a dry and tremulous tongue with thirst and sometimes unusual mental excitement or delirium soon to be followed by apathy and a comatose state.

Add to these some nausea with or without vomiting, constipation or often times a looseness of the bowels followed in a few days by gaseous distention of the intestines which may become extreme when the ileus is severe and always of bad prognostic import, various erythematous, vesicular or petechial exanthems, especially in streptococcus infections, muscular and

arthritic pains, especially in staphylococcus septicemia, the signs and symptoms accompanying the primary focus of infection, and the picture is usually complete

In the meantime there is present a sharp leukocytosis with a shift to the left, an increasing anemia with a sallow or icteroid discoloration of the skin, especially in staphylococcus and streptococcus infections, slight enlargement of the spleen and sometimes of the liver if jaundice has developed, scanty, high colored and albuminous urine and a blood culture usually positive after a day or so of incubation. Not infrequently some cyanosis is present with crepitant râles to be heard posteriorly at the bases of the lungs. Septic bronchopneumonia with pleuritis may develop. Likewise metastatic or embolic abscesses may occur in the kidneys and other organs, especially in staphylococcus septicemia, with abscesses in muscle sheaths about the shoulders, arms, legs and various joints, and with the production of periostitis and osteomyelitis. Eternal vigilance and daily examination of the patient are required because abscesses come on like a thief in the night with surprisingly few of the classical signs of dolor, calor and rubor, and they require early detection and adequate drainage.

Another thing is always certain, namely, that as long as blood cultures are positive there is some focus or foci of infection of the fixed tissues constantly feeding organisms and toxic substances into the blood so that surgical drainage is frequently of great importance in treatment whenever possible, not only of the primary focus but of secondary foci as well. Following recovery abscesses may continue to develop over months of time and especially abscesses of the muscles and bones in staphylococcus infections.

Treatment I am convinced that the treatment of septicemia will never be on a completely satisfactory basis until there is available a chemical agent or agents capable of bringing about the disinfection of the fixed tissues and blood when administered in nontoxic amounts by intravenous or intramuscular injection. Such an agent must be comparable in curative effects to the organic arsenicals like arsphenamine and neoarsphenamine in the treatment of syphilis and of other spirochetal infections. In other words I believe that chemotherapeutic research with the hope of evolving such compounds is urgently required, certainly there are no such compounds available at present although a few, to be mentioned shortly, are not without some beneficial effects. Furthermore serum therapy has not solved the problem of treatment and the general result has been that a great number of various drugs, sera and plans of treatment have been advocated with none to be particularly recommended. Space does not permit a detailed review of the enormous literature on this subject and I must content myself with a brief statement of those therapeutic procedures which I have found helpful, all of which are based upon the fundamental principles influencing infection and immunological resistance previously discussed.

In the first place adequate surgical drainage of the primary and secondary foci of infection of the fixed tissues is in my opinion of fundamental im-

portance and especially in the so-called surgical septicemias so frequently caused by hemolytic streptococci and staphylococci. This requires the very finest of surgical judgment and skill because hasty and too extensive operative measures may be meddlesome and open up new channels of infection on the one hand, while overlooking a focus or providing inadequate drainage may be disastrous on the other. On the whole, however, I believe that free drainage is the correct principle and that it is better to err on the side of too many exploratory incisions than too few. Furthermore the surgical dressings applied to accessible foci should be such as to promote the best possible drainage and in this connection I have learned to prefer hot moist dressings of hypertonic saline solution (10 per cent) or equal parts of 20 per cent saline and saturated boric acid solutions.

In hemolytic streptococcus infections I still believe in the early administration of antistreptococcus serum in adequate dosage. I doubt if such sera are bactericidal but they may contain helpful amounts of agglutinins and opsonins for the promotion of phagocytosis and likewise helpful amounts of antitoxin. A common mistake is to delay administration too long or to give too small doses. My advice is to administer serum very promptly by intravenous or intramuscular injection every 12 to 24 hours for at least four to six doses, the amount varying according as to whether concentrated or whole serum is employed, the dosage of the latter being about 30 c c by intramuscular and 50 to 100 c c by intravenous injection. There may be an advantage in testing several sera for their agglutinating titers for the streptococci secured in cultures and employing that which shows the highest titer, although the agglutinating power of a serum is not an exact measure of its efficacy, nor does the absence of agglutinins necessarily indicate that such a serum is without specific and nonspecific therapeutic value. In hemolytic streptococcus septicemias intramuscular injections of scarlet-fever antitoxin have also been used with alleged success. I have used it in seven cases of otitic origin with lateral sinus thrombosis, there were no unfavorable reactions and I gathered the clinical impression that the serum may have been of value in lessening the degree of toxemia since five of these patients recovered. In staphylococcus septicemia serum should also be administered if procurable while in pneumococcus infections due to types I and II, meningococcus, gonococcus and anthrax septicemias the prompt and free administration of the respective immune sera should be resorted to at the earliest possible moment.

Of course the necessary precautions should be observed especially when serum is given by intravenous injection. Adrenalin chloride 1:1000 is usually an effective antidote for immediate reactions when given subcutaneously or intramuscularly in dosage of 0.5 to 1.0 c c and should always be in readiness. Preliminary skin tests for allergic sensitiveness are always advisable and especially before intravenous injections. The intracutaneous test consisting of the injection of 0.2 c c of a 1:10 dilution of serum is usually employed and I generally inject the serum selected for treatment.

rather than normal horse serum. A conjunctival test consisting in placing a drop or two of 1:10 dilution of serum into one of the eyes is also employed but at this writing I am not able to express an opinion of its relative sensitivity and practical value. If either or both of these tests yield positive reactions an injection of serum should be given with special precautions, but I do not give a horse immune serum at all in any amount or by any route or method to asthmatics giving positive skin or eye reactions to such serum.

Furthermore I believe that blood transfusions are usually helpful, especially in the treatment of streptococcus and staphylococcus septicemias. It is sometimes stated that they may be harmful but I have never seen evidence of this in my experience. Personally I believe that they are always indicated and frequent small ones appear more helpful than occasional large ones. My practice is to give adults about 250 c c every three or four days for the purpose of replenishing complement and natural bactericidal and opsonizing principles as well as healthy leukocytes. When anemia is present, as it usually is in the later stages, they may be likewise helpful in combatting anoxemia by furnishing erythrocytes and hemoglobin. I have learned to prefer a direct method but the method chosen should be that with which the physician is most familiar as transfusion reactions should be avoided as much as possible and especially in very sick individuals.

In this connection it is always advisable to employ direct matching tests. Donors may be selected belonging to the same group as the patient but if time and facilities permit, the final selection of a donor should rest upon direct tests in order to avoid the regrettable error of using a donor of a subgroup. This is particularly true of Group A donors (corresponding to Group II of Moss and Jansky). I also strongly recommend in the interests of safety and simplicity dropping the Moss and Jansky classifications and employing only that of Landsteiner:

Landsteiner Group A, corresponding to II of Moss and II of Jansky

Landsteiner Group B, corresponding to III of Moss and III of Jansky

Landsteiner Group AB, corresponding to I of Moss and IV of Jansky

Landsteiner Group O, corresponding to IV of Moss and I of Jansky

Without doubt blood transfusion is a valuable part of the treatment of septicemia not only for the purpose of supplying fresh leukocytes for the elaboration of bactericidal substances if the patient's leukocytes are exhausted and incapable of immunologic response, but also for the purpose of supplying the patient with complement, as his own is likely to be reduced below normal levels.

In this connection the relative value of plain and "immunotransfusions" is commanding considerable attention but despite the fact that I have used both for many years I am as yet unable to express an opinion of value on their relative merits. The latter term was used first by Sir Almroth Wright for a method consisting of adding a quantity of vaccine, like 1,000,000,000 stock staphylococcus vaccine to about 500 c c of defibrinated blood

from a compatible donor, after waiting for about an hour the mixture was given the patient intravenously. According to Wright this procedure results in an elaboration of nonspecific bactericidal substances from the leukocytes of the donor's blood effective upon all ordinary pathogenic bacteria and not only upon the organism with which the blood had been vaccinated.

In my experience it was found that this method of "vaccinating blood in vitro" results in an increase of bactericidal activity but intravenous injections were usually followed by rather sharp reactions which I thought were caused by the bacterial protein. The therapeutic effects were due in my opinion at least in part to this nonspecific bacterial protein reaction.

Later, Colebrook and Storer suggested a method for determining whether an individual patient ought to be treated by immunotransfusion by testing the phagocytic activities of the leukocytes. If the phagocytic intake is one-third or less than that obtained with a normal blood, immunotransfusion is to be employed by the following method.

A compatible donor is given a subcutaneous injection of 1000 million stock staphylococcus vaccine and his blood used four or five hours later. Colebrook and Storer advised the use of defibrinated and not citrated blood. I have employed the method with apparent success by using direct methods of transfusion. I observed less reaction in patients and there was no danger of bacterial contamination of the blood.

Still later Hooker, Dick and others employed donors previously immunized with a vaccine prepared with the infecting organism of the individual patient. Their technic consisted in general terms of the subcutaneous injection of 500 million, 1000 million and 2000 million heat-killed bacteria on successive days followed by transfusion about one week later.

One drawback to this method is the time required for the immunization of the donor although I have found the method particularly applicable to the treatment of those cases of staphylococcus and streptococcus septicemia surviving the acute stage and requiring transfusions later on. In all instances of these septicemias it is my practice, therefore, to secure one or two compatible donors as soon as possible and start their vaccination in order to have them in readiness in from 10 to 14 days if transfusions are required as is generally the case.

At this writing, however, I am more impressed with the probable value of a method of nonspecific immunotransfusion advocated by Brody and Stephenson consisting in giving a compatible donor 50 to 75 million *B. typhosus* vaccine by intravenous injection. This usually produces a reaction of chills, fever and leukocytosis in about an hour and the blood is used three to seven hours later after the acute reaction has subsided. One drawback to the method is the unpleasant reaction in the donor requiring him to go to bed and it is therefore objectionable to professional donors. I have seen results, however, which gave me the impression that the method may be superior to plain transfusions.

Finally, since sera for streptococcus septicemia may not contain anti-

bodies for a particular strain and as antistaphylococcus serum may not be available at all, Cadham has sought to develop a method for preparing autogenous sera and administering these in conjunction with normal serum from compatible donors to furnish the complement deficiency so frequently observed in septicemia

The method adopted was as follows "The invading microorganism was obtained from blood cultures and grown in serum-glucose broth The resulting growth having been centrifuged three times in normal saline, a vaccine, in which the microorganisms had been heat-killed at the minimum lethal temperature, was then prepared and inoculated into rabbits and guinea pigs These animals tolerate comparatively large doses of a vaccine containing either streptococci or staphylococci, especially if the organisms are washed free of the media The dose of the vaccine, starting with one-quarter billion and working up to three billion organisms, was given on alternate days An agglutination titer of one to five thousand may be obtained as early as the sixth day Any time after the fifth day blood was drawn from the heart with aseptic precautions and without causing the death of the animal This blood was placed in the ice chest for eight hours, and then the serum was pipetted off The patient was inoculated subcutaneously with from 3 to 4 c c of this serum Twelve patients were treated with rabbit serum, and six with guinea pig serum There seems to have been no appreciable difference in the results obtained

"A donor whose blood was completely compatible with that of the patient was obtained as soon as possible The donor reported at the laboratory and from 50 to 60 c c of blood were withdrawn in large vacuum tubes This was left at room temperature for 15 minutes and then placed in the ice chest for 15 hours The serum was next pipetted off with all aseptic precautions, examined for sterility, diluted with equal parts of saline, and given by means of a syringe to the patient intravenously Thus, the patient received an inoculation of the animal serum containing the antibodies subcutaneously, and also received a transfusion of from 25 to 30 c c of the donor's serum containing complement Originally, the treatments were given one week apart, but this was subsequently shortened to two day intervals Treatment was continued until negative blood cultures were obtained and the patient showed considerable improvement The greatest number of treatments given to any one patient was seven

"To isolate the infective organism, culture it, inoculate the animal with the vaccine, and to await the development of amboceptors of value, required at least five days, and to obtain a serum with a more powerful agglutination titer, 12 days Frequently, the emergency of the case did not permit any such delay To overcome this difficulty some rabbits and guinea pigs were inoculated with various strains of streptococci and staphylococci Certain animals received inoculations of a vaccine prepared from 15 strains of streptococci, which had been obtained from as many different cases of local

or general sepsis. Patients were treated at once with the serum from these animals, pending the development in other animals of a specific serum."

From the standpoint of biologic therapy reference may be also made to the probable value of *bacteriophage* in the treatment of staphylococcus septicemia provided a virulent strain is available known to be highly lytic by actual laboratory test for the organism recovered from the blood. Unfortunately it is much more difficult to secure virulent bacteriophage for hemolytic streptococci and still more so for non-hemolytic strains with special reference to *Streptococcus viridans*. If bacteriophage is available I am prepared to recommend its use, especially in the treatment of staphylococcus infections. The dose may be 5 c c subcutaneously once a day or better 1 to 2 c c by intravenous injection once or twice a day. Reactions by the latter route sometimes occur but are not harmful and apparently helpful if not too severe.

Indeed I am convinced that so-called *non-specific protein reactions* are sometimes very helpful in the treatment of the septicemias, particularly if given early while the bone-marrow and other tissues of the reticulo-endothelial system have the capacity for favorable reactions. The intravenous injection of bacteriophage may have this side effect or the intravenous injection of 50 to 100 million dead typhoid bacilli may be substituted. If an autogenous vaccine has been prepared it may be used instead in doses of 25 to 50 million by intravenous injection. Otherwise one may try the intramuscular injection of 5 to 10 c c of sterilized milk but in my experience the intravenous injection of vaccine has been apparently more helpful. It is to be emphasized, however, that such agents are only to be recommended and safely used in the very early stages of septicemia and not at all in the latter stages when the patient is greatly debilitated, nor in the presence of chronic myocarditis in elderly individuals.

In this connection reference may also be made to the production of sterile abscesses by the intramuscular injection of 1 c c of turpentine diluted with 3 c c of sterile olive oil, especially in the treatment of those occasional cases of cryptogenic staphylococcus and streptococcus septicemia without discoverable primary or secondary localizations.

In addition to these measures of surgical drainage and biologic therapy recourse may be had to the intravenous injection of various chemical agents and so many have been advocated that it is at once apparent that no one of them is satisfactory. In my experience they have sometimes apparently aided in reducing the degree of septicemia but none that I know of are capable of sterilizing the fixed tissue infections which are of such fundamental importance as foci of toxin production and constant feeders of organisms into the blood. In streptococcus septicemia, particularly that of puerperal origin, I have sometimes thought that the intravenous injection of neoarsphenamine or sulpharsphenamine was helpful as suggested by Colebrook of London. The dose of either may be 0.3 to 0.45 gm dissolved in 20 to 30 c c of sterile water and slowly injected every three or four days.

Pregl's solution of iodine (concentrated) may also be tried in staphylococcus and streptococcus septicemia, the adult dose being 20 c c by intravenous injection every 24 or 48 hours. It has the advantage of low toxicity and may be safely given even in the presence of focal glomerulo-nephritis.

Rivanol in dose of 40 c c of 1/1000 solution by intravenous injection is also sometimes helpful but hardly more so than similar doses of 0.5 per cent solutions of neutral acriflavin. In my experience gentian violet in doses of 30 to 40 c c of 0.5 per cent solution by intravenous injection has not been as successful as indicated by the reports of others. However, it may be worthy of trial especially in staphylococcus septicemia but one must be sure to use the purified product prepared for intravenous injection.

The mercurial compounds must be used with caution in the presence of evidences of nephritis. I have not had the encouraging success with mercurochrome reported by many in the literature. But I still believe it may be worthy of trial in selected cases, especially in staphylococcus and *B. coli* septiciemias. The ordinary adult dose may be about 25 c c of a freshly prepared 1 per cent solution by intravenous injection or one may give 5 to 10 c c at daily intervals since a reaction does not appear necessary for therapeutic effects although in my experience best results have apparently occurred when reactions of chill, fever and leukocytosis were induced. Metaphen in dose of 20 c c of 1/1000 is much safer, produces little or no reaction and on the whole seems to be about as helpful as mercurochrome.

In addition to such biologic and chemotherapeutic treatment other measures are of great importance. Among these is to be mentioned the advisability of keeping the fluid intake to at least 3000 c c per day for adult cases and the daily intravenous injection of glucose, the average dose being 25 to 50 c c of a sterile 50 per cent buffered solution by slow injection. In some instances the continuous slow intravenous injection (*venoclysis*) of 10 per cent glucose or Ringer's solution is advisable as recommended by Hendon at the rate of no more than 200 c c per hour with interruptions in order not to exceed 3000 to 4000 c c per day. The urine should be examined at frequent intervals and the injection of glucose stopped when there is 1 per cent or more glucose present. During the height of the fever sponging with cool water is usually helpful and does much to allay mental confusion and delirium.

In the meantime the *diet* should be largely of milk, fruit juices, broths and soft foods with an attempt to furnish vitamin A and to maintain a high daily caloric intake.

It is also my custom to give one to two ounces of whiskey or brandy each day in divided doses preferably in the form of egg-nogs. Strychnine is also sometimes of service in doses of 1/30 grain two or three times a day and digitalis is occasionally required. In the presence of much pain and restlessness I do not hesitate to give pantapone and even morphine sulphate by subcutaneous injection although the latter must be used with caution if there is much distention or any nausea. Cathartics are not usually required as

daily enemas usually suffice and if there is distention these may be of 1 per cent solutions of sodium bicarbonate or about a pint of equal parts of milk and molasses at a comfortable hot temperature. Ileus is always to be feared and may be treated by such measures along with turpentine stupes for an hour and repeated every three hours along with the subcutaneous injection of 0.5 to 1.0 c.c. of surgical pituitrin every three or four hours as required. Oxygen should be given if cyanosis develops and particularly by means of a tent.

With all such measures to be considered it is easy to over-do treatment and deny the patient the greatly needed *rest* in a quiet and cool room. Indeed it is not unusual for treatment to be meddlesome in these regards and every case should have a daily therapeutic program arranged to provide the maximum of rest for the patient. It is almost impossible to foretell events and arrange treatment very far in advance, rather it must usually be arranged day by day according to individual conditions and requirements. The temperature, blood cultures and leukocyte counts are usually the best guides and blood cultures should be made every day or two whenever venapuncture is done for transfusions, the injection of glucose or chemical agents, etc.

Prophylaxis With so much to be considered in the treatment of the septicemias, especially those caused by staphylococci and streptococci, it is apparent that the methods proposed from time to time very nearly exhaust human ingenuity on this subject but yet the efficiency of a doctor in any particular case is in inverse ratio to the diversity of his armamentarium. In time, we must believe, neutralizing sera of greater efficacy will be produced, and in spite of disappointments so far, Ehrlich's "therapeuticum magnum," the intravenous drug of universal adaptation, will be discovered. But until then the need for preventive or prophylactic measures against septicemia will persist and in this connection it may be stated that a weapon of value, namely, the prophylactic use of antistreptococcus sera, is in our hands today but is not being used as frequently as should be the case.

Why should the use of antistreptococcus serum be so often delayed until severe infection is established? The immune sera are primarily prophylactics, they do not cure damaged tissues but protect those still unaffected. Furthermore their efficacy is directly related to the rapidity with which toxins are absorbed and in streptococcus infections absorption is unusually rapid. The essential is to use the serum early. If it is a good routine practice to inject antitetanic and antigangrene sera for prophylactic purposes in street accidents, although the risks of tetanus and gangrene are comparatively slight, it should be just as much a routine to administer antitoxic streptococcus serum in all cases of abnormal labor and abortion in which the incidence of puerperal sepsis is high as well as in wounds at operations on septic cases, after mastoid operations and, in fact, to any deep cut inflicted with a dirty instrument, needle pricks at postmortem examinations, etc. Little in immunology is so certain on the basis of animal experiments,

as the usefulness of such sera when given prophylactically—and their comparative uselessness when infection is well established. Neither the surgeon nor the obstetrician appears to have as yet learned these lessons. It is highly probable that the administration of such sera before or after every difficult labor and abortion would reduce the incidence and mortality of streptococcus septicemia. It is true that the patient may be made serum-sensitive but there is not the slightest reason why antisera should not be made from animals other than the horse, and in this way overcome the difficulty.

I plead therefore for the wider use of intramuscular injections of anti-streptococcus serum for prophylactic purposes and especially in puerperal and surgical cases. The dose may be 10 to 40 c c according to whether whole or concentrated sera are employed and two or three doses at three day intervals are advised.

Furthermore if septicemia is truly an infection of the blood due primarily to a complete local breakdown of barriers at the primary focus, as I believe is the case in most instances, is it not apparent that we are sometimes insufficiently drastic in surgical treatment? At first sight multiple incisions or even amputation of an arm may not seem justifiable merely for a cut finger followed by septicemia, but the price is worth paying if it is the only means of saving life. In other words a policy of undue delay in resorting to prompt and even drastic measures may result in disaster and especially in relation to prompt surgical drainage when possible and the early administration of immune sera in adequate dosage.

THE UNITED STATES PHARMACOPOEIA XI

ITS RELATION TO INTERNAL MEDICINE AND THE SCIENTIFIC NATURE OF ITS REVISION*

By VIRGIL E. SIMPSON, A B , M D , F A C P , *Louisville, Kentucky*

SCOPE

What Should the Pharmacopoeia Contain? One of the functions of the Revision Committee is to admit into the Pharmacopoeia a carefully selected list of medicinal substances of known origin, possessing therapeutic usefulness. This object differs in no essential detail from that enjoined on the Revision Committee of the first edition published 114 years ago, which stated that the object was "to select from among substances which possess a medicinal power, those, the utility of which is most fully established and best understood." In each edition from that first one to the one now undergoing revision the principle of a carefully selected list of therapeutically useful medicines has guided each succeeding Revision Committee in fixing the boundaries of its scope.

The members of the Revision Committee derive from both the medical and pharmaceutical professions, the present Revision Committee adopted, on its organization in 1930, the policy of charging the medical members of the Committee with the final decision as to therapeutic usefulness and leaving the decision as to pharmaceutical necessity and tests for purity and strength to the pharmacist members. Carrying out this policy the entire group of medical members of the Revision Committee are members of the Sub-Committee on Scope. To these 18 physicians, practitioners, teachers, soldiers, has been given the onerous task of selecting the approximately 600 substances which enter the U S P XI.

The Scope Sub-Committee must determine what yard-stick shall measure the eligibility of a medical substance for admission. Obviously, all agents used by the profession, even if possessing medicinal properties, cannot be admitted. Therefore, the Sub-Committee on Scope has determined that a substance must be a therapeutic necessity to obtain admittance. To be considered a therapeutic necessity it must appear that its usefulness is recognized by the prevailing medical opinion, that its pharmacological activity is not completely shared by a drug or drugs already admitted, that its use is, in the aggregate, large enough to make its standardization desirable, and, finally, that its composition must not be secret, nor may it be privately controlled. Not all agents possess action making them equally important therapeutically. Laboratory study, methods of assay, animal experimentation, etc., are all of value in determining drug action, but the final arbiter

* Read at the Chicago meeting of the American College of Physicians, April 20, 1934

of therapeutic usefulness must be the clinician. Where clinical opinion is uniform or unanimous with respect to the value of a drug the work of the Scope Sub-Committee is easy, but it often happens that clinical opinion is so divided that decision as to admission is difficult. In such instances the competency of observers, the accuracy of recorded observations, as well as the number of such observations, must be digested by the Committee. It follows that many drugs favorably reported on by the pharmacologist fail to achieve a permanent place in the sun.

U S P X carried 622 titles and nearly 400 of these were admitted to U S P XI without a dissenting vote. A number of the remaining have been admitted by a two-thirds vote of the Sub-Committee on Scope. Nearly 200 new titles suggested by Committee members and others and every title in the 1931 New and Non-Official Remedies issued by the American Medical Association have been studied by the Scope Sub-Committee. The number of titles that will appear in the U S P XI cannot yet be stated, as the work of the Scope Sub-Committee has not been completed, but approximately 600 will appear. The new British Pharmacopoeia (1932) has 586 titles.

As a final check for the Sub-Committee on Scope, substances occupying a neutral zone are referred to the Sub-Committee on Therapeutics, composed of nine physicians interested in therapy. If this number appears too small a group to determine matters of such great importance, the objectors are answered by the reminder that the medical profession had adequate opportunity to have a larger influence in the work of revision. Incorporated Medical Colleges and Schools of incorporated Colleges and Universities, incorporated State Medical Associations, the American Medical Association, the U S Army, Navy and Public Health Service, are each entitled to send three delegates to the Pharmacopoeial Convention. The delegates to the Pharmacopoeial Convention select the members of the Revision Committee. Nine State Medical Associations availed themselves of the opportunity to send delegates to the 1920 Convention and 26 medical schools felt a similar interest.

Deletions. That substances admitted during one revision may be omitted in some succeeding revision is but evidence of growth in medical science and the fallibility of judgment. No criticism attaches to the first factor, in fact, growth is welcomed, the second factor does not bulk large in the work of revision because of the detailed consideration given a new substance before admission and a fixed purpose to avoid radicalism. But drugs once considered a therapeutic necessity do come to be displaced by better ones, sometimes the result of added knowledge of etiologic factors, often the consequence of better understanding of pathologic processes and equally as frequently because of new developments in drug manufacture or discovery.

Acting under these broad principles substances official in U S P X have been deleted from U S P XI. About 100 titles found in U S P X have not been admitted to U S P XI. It has not appeared wise to carry impedimenta in the Pharmacopoeia and an effort is being made to eliminate

most of the titles representing unnecessary substances. The Scope Subcommittee has endeavored to have the Pharmacopoeia represent leadership in therapy and not gravitate to the lowly estate of becoming the repository of the heirlooms garnered from the field of empiricism.

Both the medical and pharmaceutical professions are apprised of proposed deletions as the work of revision progresses and arguments in favor of retaining proposed deletions are welcomed. Either the members of the medical profession have generally approved the deletions proposed or it is peculiarly indifferent, since relatively few objections have been filed. Numerous and frequent objections have been heard from the pharmacists, individually and collectively. One would expect to find the attitude reversed, but the conclusion is inescapable that physicians are content to obtain much of their therapeutic information from the pamphlet left with the sample in their offices by a representative of a manufacturing pharmaceutical house. Too small a number of physicians feel it necessary to buy new texts on pharmacology and therapeutics and the number who purchase a copy of the United States Pharmacopoeia is almost negligible.

It has been the purpose of the Revision Committee to make the Pharmacopoeia sufficiently catholic to cover all reasonable therapeutic needs. With the substances it contains any physician should be able to carry on the exacting demands of his practice regardless of specialization. It is realized that one of the reasons the Pharmacopoeia is not more popular with physicians is because of their unwillingness to write prescriptions containing the basic agents desired, with individual directions for the pharmacist for compounding. Most physicians of this generation have either never acquired or have neglected the art of prescription writing. They prefer to write for some trade-named preparation compounded by the manufacturing house. They ignore the significant weakness of fixed ingredients, of the presence of substances the patient prescribed for may not need, of the added cost to the sick to cover proprietary rights and advertising campaigns. If the costs of medical care are too high, not a little of that cost is chargeable to physicians who prescribe high-priced drugs frequently having no greater value than older or less expensive ones.

Prescription Surveys Another yard-stick with which to measure therapeutic usefulness consists in Prescription Surveys. The object of these has been to determine the actual use of both official and non-official medicines by physicians in their prescriptions. Surveys of this nature have been made at intervals since 1885 and the latest one was made in 1931 under the auspices of the United States Pharmacopoeia and the National Formulary jointly. The object of this survey was to obtain authentic information regarding the items in prescriptions and the number of times each ingredient appeared in prescriptions written by physicians and compounded by pharmacists. The survey covered many sections of the United States, hence it was fairly representative. It also was intended to discover the extent of the use of proprietaries.

One hundred and twelve thousand prescriptions were thus studied. It was estimated that 115 million prescriptions were written during the year (1931) studied. There are two ways of expressing extent of use: (a) the number of times a given drug appeared in an arbitrary group, say 5000, (b) the total number of times a substance was estimated as being used during the year. For example, a drug may be used but once in 5000 prescriptions, this appears an infrequent use, but when it is shown that such frequency means it was used 50,000 times during the year the significance is materially altered.

Some interesting features have been uncovered by this survey. United States Pharmacopoeia titles appeared in about 70 per cent of the prescriptions studied, while non-official titles appeared in 30 per cent. About 200 of the U. S. P. X titles rarely or never appeared in the prescriptions studied. The numerical rank of appearance of drugs occurring in these 112 thousand prescriptions proved illuminating. Codeine was used three times as often as morphine, sodium bicarbonate was used more than three times as often as quinine sulphate, essence of caroid was used twice as often as dilute hydrochloric acid, sodium bromide was used five times as often as sodium iodide, the tincture of gentian compound was used more frequently than tincture of digitalis, syrup of tolu was used 13 times as often as syrup of senega, unguentum hydragry ammoniati was used six times as often as unguentum sulphuris.

Such surveys are of much statistical interest, but too much significance should not be given to mere frequency of use. Codeine sulphate was prescribed 74 times as frequently as codeine phosphate. The explanation probably lies in the familiarity with sulphate salts of alkaloids. Morphine, atropine, and strychnine being old and much used drugs, have familiarized the physician with sulphates, and when he thinks of codeine he probably only thinks in terms of a sulphate. Certainly the frequency of use of the sulphate is no sort of evidence of the superiority of the sulphate over the phosphate. Tincture of gentian compound was used oftener than tincture of digitalis, but the relative value of each is not so determined. Sodium bicarbonate was used oftener than any other drug in the Pharmacopoeia, and yet one could practice medicine without it and not raise his mortality rate. Merely because doctors used Schleich's solution, and it contained opium, did not mean that opium has any local action. The greater use of infusion of digitalis does not prove it to be a superior preparation to pulvis digitalis folium.

The Pharmacopoeia should contain a list of drugs of similar action to permit of variations for obvious reasons. But the book should be a leader of therapeutic thought, not a book of antiquity.

PATENTS AND TRADE-MARKS

The Committee on Revision was instructed by the Pharmacopoeial Convention to "admit into the Pharmacopoeia a carefully selected list of

medicinal substances of known origin, but no substances or combination of substances shall be introduced if the composition or mode of manufacture be kept secret."

The Conference of Pharmaceutical Law Enforcement Officials recommended to the Pharmacopoeial Convention that proprietary medicines be not admitted into U S P XI

A privately controlled drug is a proprietary drug. Whether it is used singly or whether more than one is used, should create no confusion in the definition. Neither does it matter if the drug is well known, possesses therapeutic value and is in general use, if privately controlled it is a proprietary. Such a drug has a name and standards of strength or purity as determined by its owner, and he may alter such standards when and as he chooses. If such a drug or product is admitted under some other name or if some other standard is set up for its preparation, it ceases to be the same drug or product, in addition, if a patent or trade-mark has been issued, the Pharmacopoeia would become liable for ignoring property rights. On the other hand, if the Pharmacopoeia should admit a proprietary product with the name and standards of the owner, it has only advertised a privately controlled preparation.

However, if a drug is marketed under a controlled name, yet other houses may produce and sell it under some other name, the Revision Committee may admit it under a distinctive title if it is thought to be a therapeutic necessity. Aspirin is an example of such a product. Any manufacturing drug house may make acetylsalicylic acid and sell it under a name not already coined. The United States Pharmacopoeia may admit such a product, select a name for it and set up standards of strength and purity. Or if a privately controlled drug loses its proprietary character it may be admitted under some distinctive name. Not a few drugs now in the Pharmacopoeia had such an origin. Fowler's solution, paregoric, Lugol's solution, Basham's mixture, are well known examples of proprietary, even "patent medicines."

After much discussion the Revision Committee adopted the following general rules with regard to drugs covered by patent or trade-mark rights:

(a) A drug covered by patent or trade-mark rights should not be considered for admission unless it possesses pharmacological activities establishing it as a therapeutic necessity.

(b) No trade-marked or patented names shall be admitted. It shall be given either a chemical name or a short coined name not patented or trade-marked.

(c) The date of expiration of patent or trade-mark shall constitute a definite factor in the decision to admit or not. If the patent expires early in the decade during which the Pharmacopoeia is official, such patent or trade-mark might not prove a serious objection to admission.

(d) The approval of the patentee or trade-mark owner should be accorded to the proposal to admit a drug so controlled.

Another interesting phase of this proprietary medicine problem was the proposal to carry under the official title of a drug all of its proprietary names.

as Synonyms To illustrate Insulin is admitted to the Pharmacopoeia under the title *insulin*, it was then proposed that such a proprietary name as Iletin be carried as a synonym The manufacturers of Iletin would thus be given a costless, yet almost priceless, advertisement It is the judgment of the Revision Committee that an iodized oil should be admitted to the Pharmacopoeia Products of this nature are marketed by a number of firms, each having a distinctive trade name of its own A few examples which may be cited are Lipiodol, Lipoiodine, Iodipin Should an iodized oil be admitted it would not be wise to carry under its U S P XI title the names just mentioned as synonyms And, unless each of these products was made exactly the same way and unless each was of the same strength as the one admitted, the other trade-marked products would not be synonyms

The following extract from the correspondence with the Rockefeller Institute relative to the admission of Tryparsamide affords an insight into some of the perplexities of trade-marks and patents and synonyms

The patent and trade-mark rights relating to Tryparsamide are held by the Rockefeller Institute and the patents in the United States expire in 1935 Merck and Company has been licensed by the Institute to manufacture Tryparsamide in the United States and in certain other countries For reasons the Institute now plans to continue to allow Merck and Company the right to sell Tryparsamide under its trade-mark rights after its patent rights have expired The Institute would have no objections whatsoever to the inclusion of Tryparsamide in the Pharmacopoeia or its proper chemical name However, we would not be prepared to abandon the name Tryparsamide or to encourage the substitution of any other title which might tend to create confusion

The Revision Committee can admit this product under its chemical name or some other coined title and set up standards for its manufacture, but if the word "Tryparsamide" is not introduced as a synonym a large part of the profession would not recognize it as Tryparsamide and they would continue to prescribe the original patented article

Favoring the plan of using synonyms, it was urged that the proprietary name was often the one best known to the physician and that he could thus better identify the official drug It was further urged that such a plan would make more effective teaching the use of official drugs to medical students The Revision Committee has decided against the proposal to admit such names as synonyms by a large majority

The whole question of patents and trade-marks in medicine is becoming one of increasing importance to the profession beyond the scope of Pharmacopoeial revision One wonders if the members of the profession are actuated by impulses involving pecuniary benefit directly or indirectly to a greater degree than obtained in the generation of physicians this one succeeded The magnanimity and fine scientific spirit which gave serums and vaccines to the world contrasts strongly with the advent of *insulin*, *ventriculin*, *viosterol* or *scarlatinal toxin*

The arguments made or rather I should say the explanations offered

in justification for seeking and obtaining patent and trade-mark rights are replete with protestations of scientific interest, of jealous concern for the welfare of the sick and solicitude for the public's purse. One of these writes, "The main object in securing patents and trade-mark rights and in licensing one company to manufacture and sell the drug has been to insure to the public a product of acceptable quality at a reasonable price."

Another representing a group controlling a product writes

The function of the Committee is to protect the public as far as possible against inadequate preparations. Thus it falls within our duties to try out new preparations, if they are successful, to approve them for distribution. If they are unsuccessful, in our opinion, it is our duty to stop their distribution. We regard the public welfare as of far greater importance than any personal relationships. We shall not hesitate to institute whatever legal proceedings are indicated.

One wonders if a patent issued on a given biological product enables a committee owning the patent to censor and control all investigation of a transmissible disease problem, one wonders if a patent is intended to interfere with independent study and experiment, one wonders who protected this same public while experimental work was being done on the product for which a patent has been issued.

Studying the broad field of research medicine, it is significant that the favorite plan now is to give some university or laboratory or committee the patent and trade-mark rights and to assure the public, as well as the profession, that all profit is to be devoted to further research. Such a plan assures the individual physician immunity from the charge that he is pecuniarily interested in the product. But it does not suppress the thought that he has made himself valuable to his institution and salary increases are not impossible.

Are we drifting away from the fine spirit of our fathers? Is the beneficent altruism of the old Masters in danger of being lost?

As a means of checking the present tendency it is suggested that the patent and trade-mark laws as pertaining to medicine be modified to the extent that when and if a product be admitted to the United States Pharmacopoeia the patent and trade-mark rights end with such admission. Were this done, coupled with interim revisions, the public, concerning which such solicitous anxiety is manifested, would be adequately protected.

FEDERAL AND STATE FOOD AND DRUG ACTS

Revision of the Federal Food and Drug Act in some form will, in all probability, be enacted into law during the present Congress. The details, merits or demerits of this proposed legislation are not proper subject matter for this discussion, but the relation of the Pharmacopoeia to such legislation, both National and State, has a real significance.

The United States Pharmacopoeia is not a governmental instrument. The Pharmacopoeias of most other countries are issued by the government,

hence are governmental institutions. The United States Pharmacopoeia is made possible through the cooperative labor of the medical and pharmaceutical professions. It did not receive any sort of recognition by the Federal government until the passage of the Food and Drug Act in 1906. At that time the necessity for having standards of purity and strength was recognized and the United States Pharmacopoeia was selected as the instrument for setting up such standards. This recognition is a most unusual one in that it is the only professional contribution which has been given such distinction. Stripped of all superfluous verbiage, it means that two professions uniting in a common effort to establish high standards in what amounts to self-regulation have done so to the extent that the Federal government has adopted those standards for purposes of enforcement of Federal laws. If an added responsibility were needed to encourage each subsequent Revision Committee to carry on, this governmental relation surely affords it. Since the major portion of the work of determining standards of purity and strength has been done by the pharmaceutical members of the Revision Committees, past and present, theirs is the larger share of credit for the present status.

The National Formulary has been included in previous Food and Drug Acts as one of the standards for determining violations of the Federal Law as to purity, etc. The present and pending bill in Congress introduces another text into the enforcement picture by defining the term "official compendium" as meaning the United States Pharmacopoeia, the Homeopathic Pharmacopoeia of the United States and the National Formulary.

Since the Homeopathic Pharmacopoeia has not been revised since 1914, it would appear that the proponents of the pending legislation have peculiarly overlooked the progress of medicine, pharmacy and chemistry, for two decades. It is admittedly difficult to set up an "Official Compendium" to be used in enforcement of a Federal Food and Drug Act without, at the same time, making such texts, in effect, the law. Congress has the power, it is thought, to recognize a work as a statutory authority in existence at the time a bill is passed, it may even include supplements to such a volume. But the pending bill would make all future editions and supplements likewise the law, and by such declaration would give future Revision Committees the authority to change standards when and if deemed desirable. Since the Revision Committees of these texts are not officers of the Government, the question might well be raised, is this an "unconstitutional delegation of legislative authority?"

The pending legislation provides, in addition, that the Secretary of Agriculture may prescribe texts or methods of assay for determining whether or not a drug complies with legal standards "when such texts or methods of assay as are prescribed are insufficient" after he has brought the fact of such insufficiency to the attention of the Revision Committees of such compendium and they have failed to provide adequate standards.

The officers of the Food and Drug Administration of the Department

of Agriculture are the enforcement officers of the Federal Food and Drug Law. This group is represented by delegates to the Pharmacopoeial Convention and has participated in work of revision since. The Bureau of Standards, likewise, is represented. By such cooperation the Pharmacopoeia is made to anticipate governmental needs through interim revisions when necessary.

The tendency of the courts to admit a wider variety of proofs of illegal manufacture or shipment of drugs outside the Pharmacopoeial standards must be noted. In the recent decision of the U. S. District Court of the Eastern District of New York, in what has come to be known as the "Ginger" case, it was held that "There is no reason to hold that the non-correspondence of the extracts shipped with the standard of the Pharmacopoeia must be shown only by chemical analysis. On the contrary, it may be established in any other logical and convincing way."

This attitude is further evidenced by the statement of an official of the Food and Drug Department that in the event the Pharmacopoeia omitted certain agents, the Government would not be likely to permit such omission seriously to handicap the department in its work of preventing impositions on the consuming public.

Another interesting angle in the relation of the Pharmacopoeia to the Federal Food and Drug Act now in force has developed in consequence of the interpretation of the Solicitor of the Food and Drug Administration of what part of the text was applicable. The Act requires compliance with the "tests for quality, purity and strength" as laid down in the Pharmacopoeia, but the Solicitor has ruled that this be interpreted as excluding such parts of the text as definitions, formulae and descriptions.

In the case of some titles in the text the definition and the description are important as to identification and even standardization. It has been quite generally accepted that the whole text of a drug was intended to be used for the establishment of uniformity, as well as efficiency.

To meet this situation it is proposed to introduce in the forthcoming Pharmacopoeia a "General Notice" definitely stating that all sections of a monograph, unless specifically exempt, are to be recognized as a part of the standard.

"INTERIM REVISION"

It is recognized by physicians, pharmacists and government officials alike that a decennial revision of the Pharmacopoeia does not keep it abreast of scientific medical development. Many new data accumulate, now, in a 10 year period, new therapeutic agents come into use at a rapid rate and refinements of manufacture, assay, etc., render old methods and standards rapidly obsolete. To appreciate the extent of this development one needs but to call to mind a few illustrations: liver extract, insulin, vitamins.

The cost of more frequent complete revisions, encompassing the issuance of an entirely new book, is prohibitive. If sectional revisions be

done the difficulty of giving them a permanent form, as well as necessary publicity, becomes a matter of practical importance. Even when the new matter involves the admission of a new agent and even if added as a "supplement," the matter of indexing offers a problem. If the change applies to but a part of the text on a given agent, the difficulty becomes appreciably more intricate.

A loose-leaf type of book, allocating one or as many sheets as necessary to each separate subject, permitting removal of the old text and insertion of the new, would seem to be the simplest method for keeping the text up to date. A nominal charge could be made for newly-revised sheets, a revised index could be made yearly and supplied each subscriber. The plan at present agreed upon to keep the U S P XI revised consists in (a) issuing a printed supplement on the first of each year, (b) the statement that each change so made becomes official on January 1, coincident with issuance, (c) that as changes are decided upon announcement be made in the medical and pharmaceutical press of the country, (d) that the supplements be of uniform size with the original text, (e) that a revised index be issued with each annual issue of supplements, (f) that a binder be supplied for the preservation of supplements as issued, (g) that a page of coupons be included in the original copy of the U S P XI, the owner of the book to fill out a coupon for each annual supplement revision, which enables him to obtain from the publisher a copy at a nominal cost, (h) the issuance at the end of five years of the original volume with all interim revisions included. This latter proposal has not been definitely determined.

The success of such a general plan of interim revision would depend upon many factors wholly beyond the control of the Revision Committee and the Board of Trustees. If the owners of the volumes did not cooperate to the extent of both obtaining and preserving the copies of interim revisions, much confusion and error would obtain. In court procedure for example, the necessity for establishing the text of the copy of the U S P XI revised to January 1 of the current year would be obvious. Another problem is presented in the books on pharmacology used by physicians and students. The text of these books is based on the United States Pharmacopoeia and the authors would meet a practical difficulty in dealing with interim revisions.

The advantages, however, are so obvious that making the plan of interim revision workable becomes a necessary duty and its accomplishment will be the outstanding achievement of Pharmacopoeial revision. Reference has been made to some of the necessities for and advantages of an up-to-date Pharmacopoeia under the section of this paper on the scope of the Pharmacopoeia.

ORIGINAL STUDY

In revising the Pharmacopoeia the medical and pharmaceutical literature is studied so that the last information available on all subjects may be

utilized. This applies to such subjects as are admitted because of therapeutic usefulness, as well as pharmaceutical necessity. Supplementing such study as the Committee on Revision has time or qualification for doing, the By-Laws of the United States Pharmacopoeia Convention authorize the employment of experts in the various fields studied. These studies began as early as 1926, preparatory to the revision of the present Pharmacopoeia.

The advantages of this plan are apparent, but three merit emphasis in the present discussion. (1) Such workers are already familiar with the current literature on the given subject, as well as the technical aspects involved. (2) By enlisting the interest of scientists, practical workers and students, as well as universities, colleges and laboratories, a greater and more general interest in the Pharmacopoeia is obtained. (3) Such coordination and intensive study means a saving in both time and money. Approximately \$10,000 have been expended on this phase of the work of revision for the coming issue.

In addition to these groups of experts the services of another valued group have been made available through the cooperation of auxiliary members. These auxiliary members were individual physicians, pharmacists and scientists who were invited by the Revision Committee to cooperate in the work of revision because of special qualifications or interests. More than 200 auxiliary members have been elected to these positions and their contributions have been noteworthy.

Yet a third group has done yeoman service in the work of revision. The United States Pharmacopoeia is the legal standard for the Philippines, Puerto Rico and Hawaii and the adopted standard of the Republic of Cuba. Representatives from these islands have, on invitation, participated in the work of revision.

Finally, the work of revision has been materially advanced by the cooperation of the Pharmacopoeial Committees of Great Britain and of Continental Europe. Switzerland, Holland and Germany have issued new Pharmacopoeias since 1926 and much of their new material has been translated by the Committee of U. S. P. XI for study by the various sub-committees.

VITAMINS

An optional method for the biological assay of one of the potent principles of cod liver oil was included in the U. S. P. X. By this act the United States Pharmacopoeia took advanced ground ahead of the Pharmacopoeia of other countries.

This method of assay was (a) optional, (b) provided that oil should contain "at least 50 units per gram," (c) provided for vitamin A assay only.

It therefore, did not establish a standard of A potency, but rather determined the lowest value an oil might have to permit labeling as a United States Pharmacopoeia product. Neither did it recognize the D

content of cod liver oil. The method of biological assay established as the end point the relief of symptoms of vitamin A starvation in young albino rats with a specified gain in weight during the test period. The cure of xerophthalmia has been urged as a superior biologic criterion, while such a criterion is more convincing qualitatively, it is more indefinite quantitatively than the criterion of growth recovery for a 35-day period.

A presumptive defect in the method of the U. S. P. X lay in the influence which other possible factors might have over the weight decline of the test animal while vitamin A was withheld, as well as such influence on the weight recovery period during the cod liver oil feeding period. One need merely mention the physical character of the ration, the amount of protein consumed and the presence of vitamins B and D.

An assay method for vitamin D had also become a necessity by virtue of increasing knowledge of its importance. The method of basing the unit for A on the daily dose, while the unit for D was based on the total dose, gave results indicative of a marked apparent discrepancy in A and D content in a given sample of oil. Some method whereby this apparent discrepancy might be reconciled was urgently needed.

Another important question in the biological assay of cod liver oil concerns the quantitative interpretation of the data of A and D assays. In all bio-assay work a certain deviation of biological response is usual. In other words, should this deviation response be ignored or made use of by specifying the unit dose in terms of percentage of positive responses? Further, some appreciation of the importance of the variations of statements on the labels of different brands of cod liver oil was made necessary because of differences in standards for potency adopted by the various distributing firms. Likewise, some uniformity in labeling was recognized as a necessity. Some firms labeled their product in terms of units per gram, others in terms of units per ounce. This lack of uniformity was confusing alike to the doctor, the druggist and the patient.

The Permanent Commission on Biological Standards of the Health Organization of the League of Nations has issued a standard for vitamins. The United States has a representative on this Commission.

Through its Board of Trustees the U. S. P. XI is cooperating with the medical and pharmaceutical professions of other countries to reach an agreement on an international standard for vitamins.

The Pharmacopoeia has set up a Vitamin Advisory Board, this includes a group of laboratories now engaged in the work of developing satisfactory vitamin assay methods for vitamins A and D. A composite sample of cod liver oil labeled "reference cod liver oil" has been distributed among the workers to be used as a standard of comparison in assaying the vitamin content of both foods and medicines. The members of the American Drug Manufacturers Association, the Federal Food and Drug Administration and a number of laboratories in various universities are cooperating with the U. S. P. XI in this work. Without this contribution on the part of

vitamin experts the expense of this work would be large enough to make it impossible for the Pharmacopoeia to carry it on

The most important question touching the work on the biological assay of cod liver oil for A is the criteria of A deficiency in experimental animals. None adopted thus far are 100 per cent perfect and are, at best, a matter of comparison.

The following standard has been recommended for adoption.

The new U S P XI vitamin A units are to be identical with the international units. The minimum vitamin A standard for U S P XI cod liver oil shall be not less than 600 international units.

The study of vitamin D has led to the recommendation that its potency in cod liver oil should also be expressed in terms of units. A unit is to be defined as the minimum average daily amount of cod liver oil required to produce a continuous narrow line across the metaphysis of a leg bone in four out of six rats in each group prepared under conditions specified for the assay.

It is well known that cod liver oil shows much less variation in its vitamin D potency than it does in vitamin A content. Notwithstanding this relative uniformity the British Medical Research Council has recommended the adoption of a standard ergosterol solution to serve as a measure for vitamin D potency of substances containing or claiming to contain this vitamin. This ergosterol was prepared from yeast by drying and dissolving in alcohol and subjecting the end product to irradiation from a mercury arc lamp. It was found that such a preparation was soluble in olive oil and retained its potency unchanged for as long as two years if kept below 0° C. The British Medical Research Council has recommended that the potency of this antirachitic substance be measured in terms of units and that either the roentgen-ray, "Line Test" method or chemical analysis of bones of experimental animals be used in estimation of vitamin D.

The Council defines the unit of vitamin D "as the antirachitic potency of a quantity of irradiated ergosterol corresponding to 0.0001 mg. of the ergosterol used in its production." One cc. of their standard solution, therefore, represents 1000 units of vitamin D activity.

The chief commercial supply of vitamin D in this country comes from irradiated ergosterol. Through the Council on Chemistry and Pharmacy of the American Medical Association this substance has come to be known as Viosterol. It is dispensed in a vegetable oil and is about one hundred thousand times as potent as an antirachitic as cod liver oil.

The Special Committee of the U S P XI has recommended that the minimum vitamin D standard for the U S P XI cod liver oil shall be not less than 85 international units.

Latterly much discussion has accumulated in the files of the Revision Committee concerning the definition of cod liver oil. A three-cornered discussion has just been concluded the participants being the officials of the Bureau of Fisheries, the Food and Drug Administration and the Sub-

Committee 8, of the Revision Committee U S P XI The point at issue was whether cod liver oil should be defined in the interim revision text as "the fixed oil obtained from fresh livers of *Gadus morrhua* Linne and of other species of *Gadus*" or "other species of the family Gadidae"

To the average physician it might seem a mere peccadillo whether the oil he prescribes for Junior sprang from the royal "species of *Gadus*" or emanated from the plebeian "family Gadidae" No doubt even Junior would be disdainful as to the source of his daily vitamin A, paraphrasing Shakespeare in asserting that "Cod liver oil from any other source would smell as malodorously" In this discussion commercial interests, as usual, took a hand The total domestic consumption of cod liver oil is nearly five million gallons, an average of two-thirds of a pint for each man, woman and child in the United States and her colonial possessions¹ Ninety-four per cent of this oleaginous river flows into the States from foreign countries, two countries, Norway and Newfoundland, supply 72 per cent of our imported oil These countries restrict the source of the oil to the genus *Gadus* To them the family Gadidae is anathema

To the Revision Committee the vitamin content and the esthetic qualities of the oil must be assured—the rest is twiddledee or tweedledum

COLOR STANDARDIZATION

Color, at first thought, appears simple and elemental White light passed through a prism and projected on a screen produces a band of light called a spectrum This spectrum presents a range of colors with violet at one end and red at the other, while indigo, blue, green, yellow and orange lie between, in the order named The shades between these primary colors which the eye can recognize and name are a bit limited, they are estimated at from three to 130

The U S P X used 287 different color names The importance of a color standard is recognized by the fact that these color names are used more than 2400 times in the book During the 10 year period following the last revision some research study was authorized by the Board of Trustees The result of that study was a very instructive color exhibit by the Committee at the Pharmacopoeial Convention May 13, 1930 During the session of the Convention the first Color Conference was held and more than 100 experts participated in the work of establishing workable standards for color estimation and uniformity in nomenclature Out of this Conference developed an "Inter-Society Color Council," to which representatives were accredited to chemical, architectural, physical, optical, engineering, pulp and paper, painters and decorators and motion picture societies More than a score of private individuals interested in color description and specification also participated

While the United States Pharmacopoeia initiated this study, it is evident that no marked changes in nomenclature could be made without the co-

operation of the many diverse interests of art, science and industry. In short, in the language of the Chairman, the definitions on limitations of color names should be "so accurate that science will accept them, so broad that science, art and industry can use them, so popular that the public can understand them."

The Pharmacopoeia is interested in two primary color problems, (a) the scientific standardization of color names, (b) the background color of "poison" labels. Experts are now at work checking the color names used in the coming text of the U. S. P. XI, correlating it with the color nomenclature being studied by the Council as a whole. This accomplishment will make the U. S. P. XI the first scientific publication to carry a color nomenclature based on a scientific foundation.

PERCENTAGE SOLUTIONS

When a physician writes a prescription for a preparation in solution in a given per cent he thinks he has given the pharmacist as specific directions as are necessary. As a matter of fact, the pharmacist recognizes that the term *per cent* has different meanings when used under varying conditions. He wonders if the physician means the sum of the percentages of the ingredients or the composition in terms of the finished product. The physician probably thinks, as a matter of mathematics, that the sum of percentages of ingredients means 100. The pharmacist remembers that a 10 per cent solution of sodium chloride may contain 95 per cent of water. Again, the physician writes for a "saturated solution" of potassium iodide and later the same order is written for sodium iodide. When the patient takes 30 drops of the first he is taking a solution containing 103 per cent of potassium iodide, while in the latter prescription there is 120 per cent of sodium iodide.

To obviate some of the uncertainties in prescription work it is proposed to carry under the caption, "General Notices" of the forthcoming Pharmacopoeia a statement somewhat as follows:

Per cent weight in weight to be expressed by the symbol W/W and means the number of grams of an active ingredient in 100 grams of the solution.

Per cent weight in volume to be expressed by the symbol W/V and means the number of grams of an active ingredient in 100 cubic centimeters of the solution.

Per cent volume in volume to be expressed by the symbol V/V and means the number of cubic centimeters of an active ingredient in 100 cubic centimeters of the solution.

That the expression per cent when used without qualification is to be interpreted as meaning for solution of solids in liquids, per cent, weight in volume, for solution of liquids in liquids, per cent, volume in volume, and for solutions of gases in liquids, per cent, weight in volume.

These terms are equally applicable to the metric and apothecaries' systems, e. g., a 1 per cent solution prepared under the metric system would contain one gram of a solid or one cubic centimeter of a liquid in enough of the

solvent to bulk 100 cubic centimeters of the finished product When prepared under the apothecaries' system 4.6 grains of a solid or 4.8 minims of a liquid in enough of the solvent to bulk one fluid ounce of the solution

Of course, in pure science percentage composition tables are expressed in terms of per cent by weight It is not common practice, however, in the United States to weigh liquids Some sanction to the proposed recognition in the U. S. P. XI may be found in the recommendation for adoption by all State Boards of Pharmacy of such a method by the National Association of Boards of Pharmacy, the adoption of such a method by the Conference of Pharmacy Teachers of the American Association of Pharmacy Colleges, the definition of percentage solutions and acceptance of the metric W/V solution in the book, "Useful Drugs," published by the American Medical Association for the guidance of faculties of medical schools and State Medical Examining Boards It may be further noted that the British Pharmacopoeia of 1932 introduced a similar statement under the heading, "General Notices," in an effort to establish uniformity in practice The introduction of such a statement as proposed into the U. S. P. XI will give official sanction to the metric W/V basis for making percentage solutions and make prescribing more definitely uniform

EDITORIAL

CHEMICAL FACTORS IN THE BEHAVIOR OF THE VEGETATIVE NERVOUS SYSTEM

WITHIN the past decade a new concept of the method of transmission of the effects of nerve impulses has developed. Dale recently has summarized the contributions and development of knowledge in this field. The first suggestion that a chemical agent acted as an intermediary between nerve stimulation and effector response was made by Elliot in 1904. After noting the similarity between the action of epinephrine and the stimulation of sympathetic nerves, he postulated that sympathetic nerve fibers liberated epinephrine at their endings, the epinephrine, he implied, might be the chemical intermediary between nerve impulse and effector response. Dixon was the first to suggest that the parasympathetic nerves might also release a chemical substance at their termination. The lucid experiments of Otto Loewi, in 1921, demonstrated for the first time the tenability of the foregoing hypothesis. He showed that the vagus nerve of the frog produced its effects on the heart by liberating an inhibitor substance which he termed "Vagus Stoffe". The fluid obtained from such a heart could be transferred to another heart, and again would exhibit an inhibitory or vagus effect. Loewi found this inhibitor or vagus substance corresponded to acetylcholine by all known tests.

The investigation of the part played in physiology by this derivative of choline forms an interesting chapter in medical research. Acetylcholine was synthesized by Baeyer in 1867, and its intense physiologic properties were discovered by Hunt and Taveau in 1906. It was not until 1914, however, that it was known to occur in nature, when Dale found it present in a sample of ergot. At this time Dale noted the remarkable similarity between the action of this substance and the effect of stimulation of the parasympathetic nerves. Acetylcholine causes inhibition of the heart, increase in intestinal tonus, and dilation of small arterioles. These actions can be abolished by atropine. It also has a third type of effect similar to nicotine, that is, there is a rise in blood pressure which is presumably due to stimulation of sympathetic ganglia, together with liberation of epinephrine.

Acetylcholine was first isolated from the animal body in 1929 by Dudley and Dale, who found it in extracts of the spleen of the ox. Recently, Chang and Gaddum have found it present in large amounts in the placenta of women. In an analysis of various body tissues they found the largest amount of "acetylcholine equivalent" in those tissues, the activity of which is controlled by the parasympathetic nerves.

It is almost certain at present that acetylcholine is the chemical transmitter of parasympathetic effects. Englehardt obtained a substance after reflex production of the autonomic actions of the third cranial nerve, which was similar to Loewi's "vagus substance" and presumably was acetylcholine.

Similar results have been obtained from stimulation of the chorda tympani nerve. Dale and Feldberg collected the substance released in the wall of the dog's stomach after stimulation of the vagus nerves and found it to correspond entirely to acetylcholine.

The fact that stimulation of the sympathetic nerves released a chemical substance was also first demonstrated by Loewi. The vagus nerve in the frog contains some sympathetic fibers, and at times stimulation caused acceleration of the heart. In these instances he found that the fluid from the heart transmitted an accelerator or epinephrine-like effect to another heart. Cannon and his coworkers recently have shown that, in a suprarenalectomized animal, stimulation of the lower end of the sympathetic chain caused release into the blood of a substance producing sympathetic stimulation in other organs. This substance closely resembles epinephrine. Cannon has called this substance sympathin and has expressed the belief that it is not identical with epinephrine. He stated that there are two types of sympathin: (1) Sympathin E, given off by smooth muscle which is stimulated to contract by sympathetic impulses and (2) Sympathin I, given off by smooth muscle which is inhibited by such impulses. Bacq has demonstrated that stimulation of the cervical sympathetic nerves causes release of a substance in the aqueous humor which is either epinephrine or closely related to it.

All evidence to date, then, points to acetylcholine as the chemical transmitter of parasympathetic effects and epinephrine or a closely related substance of sympathetic action. There are outstanding exceptions to this rule, so that Dale suggested the terms "cholinergic" and "adrenergic" to indicate the function of nerve fibers. The sweat glands of the cat and of the hand of man, although supplied by fibers of sympathetic ganglion cells, respond but little to epinephrine, but are stimulated to secretion by pilocarpine or acetylcholine. Feldberg and Dale showed that stimulation of the sympathetic nerve supply to the foot of the cat caused liberation of acetylcholine. These fibers are therefore cholinergic.

The mode of transmission of nerve impulses across synapses has never been well understood, nor has it been explained how the nerve impulse passes from motor end plates to voluntary muscle. Recent evidence indicates that acetylcholine may intervene in both these situations. Kibjakow perfused the superior cervical ganglion of a cat, and found that something appeared in the fluid after stimulation of preganglionic nerves which on reinjection acted as a stimulus to activity. In other words, impulses are transmitted across a synapse by release of this substance. Feldberg and Gaddum, using the same technic, showed that the substance was apparently acetylcholine. It is interesting to note that stimulation of the splanchnic nerve to the suprarenal gland caused acetylcholine to appear in the blood of the suprarenal vein (Feldberg and Minz).

Acetylcholine is known to stimulate certain voluntary skeletal muscles in lower vertebrates and in mammals after the motor nerves have degen-

erated Recently, Feldberg and Dale have shown that stimulation of the hypoglossal nerve (after causing the sympathetic fibers normally present in it to degenerate) results in the formation of acetylcholine

It seems probable from the mass of evidence accumulating that chemical substances are released at all cytoneural junctures in the periphery to act as transmitters of nerve impulses Perhaps the same is true of synapses in the central nervous system Dikshit recently showed that a small amount of acetylcholine injected into the intraventricular fluid caused effects on respiratory activity similar to central stimulation of the vagus nerve

The discovery of the substances concerned in chemical transmission of nerve impulses opens up a new field for clinical research and therapeutics Acetylcholine itself is not useful clinically, as its action is too evanescent, and it must be given intravenously Recently new derivatives of choline have been synthesized One of them, acetyl- β -methylcholine, can be given orally and subcutaneously, its effects are less transitory, and it may be useful in certain diseases or disturbances of cholinergic nerves This concept of the behavior of nervous activity will help to clarify many puzzling phenomena observed in disorders affecting the vegetative nervous system

REVIEWS

Acute Intestinal Obstruction By MONROE A McIVER, M D, Surgeon-in-Chief, Mary Imogene Bassett Hospital, Cooperstown, N Y 430 pages, 19 × 26.5 cm Paul B Hoeber, Inc, New York City 1934 Price, \$7.50

This monograph contains a very complete presentation of both the experimental work upon the consequences of acute obstruction, and the clinical aspects of this condition. The toxic, bacterial and splanchnic paresis theories are discussed and full references given to the literature. The clinical and pathological varieties of obstruction are described in detail. There is a very complete and valuable presentation of the problems associated with diagnosis and treatment. The investigator who is interested in this field and the practicing clinician will find this a helpful study of an important subject.

C H

The Medical and Orthopaedic Management of Chronic Arthritis By RALPH PEMBERTON and ROBERT B OSGOOD vii + 403 pages, 15 × 22 cm The Macmillan Company, New York 1934 Price, \$5.00

In this book Pemberton and Osgood have quite thoroughly covered the single type of arthritis known as Chronic Arthritis. Of the 14 chapters, six are devoted to the various phases of treatment, this is as it should be since "what to do" is more important to the patient than "what is it?" Encouragement is given to the patient rather than the opposite which is so often the case.

Chapter II presents the evolution of the terms of classification since 1857 and ends by offering the two most commonly accepted division titles, atrophic and hypertrophic. These names are both descriptive and simple and they avoid the weakness of the so often attempted, but rarely completed, efforts to classify strictly according to etiology, or pathology, etc.

The pathological and physiological phases of the subject are fully covered. Unfortunately the physiology is not as clearly understood as is the pathology due to the differences in availability of material, etc., but a complete analysis of the many theories is presented with a brief explanation relative to the authors' views on each phase.

The six chapters on treatment are quite extensive and cover practically all available methods for the alleviation of the disease. The value of each method is weighed on the scales of the authors' experience which is extensive. Emphasis is placed upon the fact that no cure-all is now known for chronic arthritis and that the results of treatment are dependent upon slow, painstaking, and consistent work with one or more methods. Strength is placed upon the upbuilding of the body in general and the care of all system functions, especially posture and bodily activities, and the gastrointestinal tract.

This book offers a complete review of the subject of chronic arthritis from as nearly an unbiased and neutral standpoint as is possible. At times the discussion seems a trifle diffuse. Due emphasis is placed upon the necessity of a minutely careful survey of the individual as a whole, weighing the relative values of the abnormalities discovered. It is pointed out that in most cases improvement will be attained if a careful and thorough routine is followed. The vital importance of early diagnosis and of early treatment is stressed. In the convincing presentation of the foregoing fundamental principles lies perhaps the chief value of this interesting monograph.

A V

An Introduction to Sex Education By WINIFRED V RICHMOND, Ph D, Psychologist, St Elizabeth's Hospital, Washington, D C 299 pages, 14 × 21 cm Farrar and Rinehart, Inc, New York City 1934 Price, \$2 50

This is the third book that Dr Richmond has written on the subject of sex education, yet there is very little that is repetition in this series. This latest book is an attempt to clarify the thinking on the whole subject and to give a concise and scientific discussion of the problem. Although Dr Richmond is a psychologist, she has had a broad experience with abnormal as well as normal psychology, and has been closely in association with the medical group at the federal hospital, and it is evident from her references that she has widely read the medical literature on the subject under consideration.

In these chapters she discusses general biology, biology of reproduction in man, sex in primitive society, marriage and the family, psychology of sex, specific problems preventing proper adjustment in sex, and problems complicating marriage. In her final chapter she very sanely presents a program of education. The physician will find this is a book that he can safely recommend to his patients without the fear of creating morbidity.

Clio Medica German Medicine By W HABERLING, M D, translated by JULES FREUND, M D 160 pages, 11 × 17 cm Paul B Hoeber, Inc, New York City 1934 Price, \$1 50

The Clio series of small volumes on various phases of medical history has recently had two new volumes added. The one under consideration, by the erudite professor of medical history at Dusseldorf, is a masterly presentation in small space of the achievements of German and Austrian physicians in the fields of medicine, surgery and the specialties. The amount of knowledge added by the Teutons is indeed remarkable. One need only glance at the names Paracelsus, Friedrich Hoffman, Stahl, Haller, van Swieten, Johannes Muller, Theodor Schwann, Virchow, Koch, von Behring, Ehrlich, Rontgen, Pettenkoffer, von Graefe—to mention just a few of the outstanding ones.

The growth of medicine in Germanic lands is traced from the crude beginning in the ancient times, through the middle ages and the fruitful eighteenth and nineteenth centuries down to the present much specialized age. Haberling misses the great contribution made unwittingly by Hahnemann, in that he showed us the natural history of disease uninfluenced by drugging and so eventually pointed the way to a more sane therapy. The editor of the series makes good the omission in a footnote.

This series of books which can be put in the pocket is a splendid undertaking and should do much to popularize the much neglected subject of the history of medicine, a full knowledge of which renders full of meaning the trends of medical thought as we see them today. This is a worthy companion to the preceding volumes.

J R

The Mother's Encyclopedia Edited by MARY E BUCHANAN, managing editor of *The Parents' Magazine*. Articles contributed by 130 authors. vii + 959 pages, 4 vols, 12 × 18 cm Home and School Book Service, The Parents' Publishing Assoc, Inc, New York City, N Y 1933

This encyclopedia is unique in that it is the first time that an attempt has been made to publish in book form a series of articles covering the whole field of child care from the parent's viewpoint. The editor of this four-volume set of books has gathered articles written by some of the foremost authorities in the field of child health and training, child psychology, nutrition, sex education, family relationships,

play and play equipment All the articles at one time appeared in *The Parents Magazine*, but these articles have been condensed and edited wherever necessary to bring them strictly up to date Cross references under every subject, sub-titles on nearly every page and a voluminous index in the final volume make it possible to find quickly any subject under consideration

Of the 130 men and women who have contributed to this encyclopedia, 31 are physicians The articles are written in a sane and scientific manner without the usual hodge-podge that is so frequently found in books on health written for the laity There is nothing said that would lead patients to self-medication, as is the usual result of lay reading of medical articles Physical health is fully discussed, but the largest number of pages is taken up in the discussion of child guidance and the emotional development of the individual

At the end of the encyclopedia is a table of contents grouped by age interests infancy, pre-school age, school age, adolescence, all ages and parenthood Under infancy are such articles as Bathing the Baby, Weaning the Baby, Respiratory Diseases, and Fear In the second grouping are such articles as Enuresis, Habit Training, Night Terrors, Sleep Routine, Thumbsucking, and Answering Children's Questions In the school age group some of the articles are How to Choose the Right School, Physical Growth, Home Study, Creative Education, and Social Training Under adolescence are such subjects as The Foods Needed, Friction in the Family, Cosmetics, Delinquency, Scouting, Nervous Breakdowns, Love, and Vocational Guidance Some of the other titles picked at random are Budgeting the Family, Convalescent Occupations, Adoption, How Big Should a Family Be, Maternity Clothes, Eye Protection, Divorce, Dancing, Masturbation, Obedience, and Health Guidance

Since most physicians are parents and as puzzled over the problems of bringing up children as their lay patients, the physician will find considerable help in this encyclopedia as well as a good deal of interesting reading, which will give him a better insight into the problems he is so frequently consulted about

Klassifikation der Schizomyceten (Bakterien) Versuch einer wissenschaftlichen Klassifikation der Bakterien auf botanischer Grundlage By PROF DR ERNST PRIBRAM, D Z Professor für Bakteriologie und Präventiv-Medizin an der Loyola University, School of Medicine, Chicago, Illinois Paper, 143 pages Franz Deuticke, Leipzig and Vienna 1933

The investigators to whom bacteriology owes its rapid development during the latter part of the last century were untrained in taxonomy and the rules of biological nomenclature The results were quite naturally the frequent adoption of faulty names for bacteria and the lack of an adequate and satisfactory system of classification A number of attempts have since been made to correct these errors but the suggested changes have not had official sanction On the other hand these newer names and more recent systems have been used by some authors, while others retain the older terminology and classification This has led inevitably to a condition bordering on chaos in the fields of nomenclature and taxonomy Pribram now presents a new system This monograph represents the work and experience of some 20 years and offers a classification differing materially from that suggested in 1929 by the same author In his terminology he follows quite strictly the biological code and also leans heavily on the suggestions offered by the Committee of the Society of American Bacteriologists

In his classification the author makes use of the work of his predecessors but has deviated from their systems in many ways He has attempted to meet the requirements of exactness and elasticity, the latter by the use very largely of only one attribute as a characteristic of a group and by making subdivisions for each character

This elasticity is wanting in former classifications which thus allow no place for transitional forms or for new hitherto unknown species

The author's monograph is in two parts, preceded by a tabular synopsis of schizomycetes. The first explains this table and discusses the nomenclature and classification. The second part is devoted to the classification of the cultures of bacteria at present in the Kral collection in Vienna. There is an excellent index and an extensive bibliography.

Pribram divides the bacteria into three subclasses: algobacteria, eubacteria, and mycobacteria. The algobacteria include those forms adapted to life in water, and some of the parasitic and pathogenic microorganisms. This subclass contains organisms transitional between bacteria and algae, and others bridging the gap between the bacteria and the protozoa. The algobacteria are arranged in their various families distributed among four orders. The eubacteria include most of the "true bacteria" not placed in the first subclass, they are arranged in five families under two orders. The mycobacteria are subdivided into two orders. One of these contains the aerobic and the anaerobic, spore-bearing bacilli, each in a separate family, and the other, distributed between two families, most of the bacteria recently grouped in the order actinomycetales by Bergey and others.

In comparing the classification adopted by Pribram with some of the other modern systems we find many divergencies. Thus, whereas in the latter, the sulphur bacteria are placed in a single order, here they are distributed among several orders of the algobacteria. Again, the "slime bacteria" are generally arranged in a single family but are here placed among the algobacteria in two families. Indeed, one of the genera (*Myxococcus*) is found in the same family with *Vibrio cholerae* and *Ps. aeruginosa* (*B. pyocyaneus*), a rather startling juxtaposition. Also the spirochetes are put in an order of the algobacteria containing some of the sulphur bacteria, although in a different family, it is true. The cocci, which heretofore have all been classified in a single family, are found distributed among several families of algobacteria and eubacteria. Whereas most of them are classed in the first of these groups, the streptococci, including the pneumococcus, are discovered in the same order, but in a different family, of eubacteria as the proteus and acidophilus groups. The genus *Neisseria*, however, because of its strict adaptation to the animal organism, is placed in a family of the eubacteria with the brucella, the hemorrhagic septicemia, and the hemoglobinophilic groups. The classification of the spore-bearing bacteria removes them further from the other "true bacteria" and brings them into closer relationship with the tubercle bacillus, the diphtheria bacillus, and the actinomycetes than is usual. Also in the arrangement of the genera of actinomycetales in families, Pribram differs from the Committee of the Society of American Bacteriologists and from Bergey. These citations give some indication of the degree to which the classification offered in this monograph diverges from former systems. The author publishes his work in the full knowledge that it will call forth much opposition and criticism. May this discussion serve to stimulate interest in the solution of the problems and hasten the day of the adoption of a definitive system of taxonomy.

F W H

COLLEGE NEWS NOTES

Acknowledgment is made of the following gifts to the College Library of publications by members

Dr Elliott P Joslin (Fellow), Boston, Mass—1 book, "Diabetic Manual"

Dr Samuel M Feinberg (Fellow), Chicago, Ill—1 book, "Allergy in General Practice"

Dr Joseph R Darnall (Fellow), Ancon, C Z—2 reprints

Dr C Glenville Giddings (Fellow), Atlanta, Ga—1 reprint

Dr Arthur H Jackson (Associate), Washington, Conn—2 reprints

Dr Henry S Houghton (Fellow), Chicago, Ill, has resigned as associate dean of the Division of Biological Sciences and director of the University Clinics, University of Chicago, to become advisory representative of the China Medical Board, beginning January 1, 1935 Dr Houghton was formerly dean of the University of Iowa College of Medicine The China Medical Board, as an agency of the Rockefeller Foundation, owns and supports the Peiping Union Medical College

Dr Phillipp Schonwald (Fellow), Seattle, Wash, addressed the Rocky Mountain Tuberculosis Conference, Colorado Springs, Colo, September 17 to 19, on "A Modification of the Blood Sedimentation Test in Tuberculosis"

Dr Harold S Davidson (Fellow), Atlantic City, N J, has been selected as General Chairman for the annual meeting of the American Therapeutic Society, meeting in Atlantic City, June 7 to 8, 1935

Dr Zacharias Bercovitz (Associate), formerly of the Pyengyang Union Christian Hospital, Pyengyang, Chosen, Korea, has completed some postgraduate work at the London School of Tropical Medicine and announces he will resume practice at 889 Lexington Avenue, New York City Dr Bercovitz has been appointed to the clinic staff in gastro-enterology of the New York Post Graduate Medical School and Hospital

Dr Seale Harris, Jr (Associate), Nashville, Tenn, has been promoted to associate professor of medicine at the Vanderbilt University School of Medicine

Dr Rock Slevster (Fellow), Wauwatosa, Wis, was the recipient of the gold seal of the State Medical Society of Wisconsin at their annual dinner, September 13 Dr Slevster is editor of the state society's journal He was formerly president and secretary of the society, and he is now vice-chairman of the Board of Trustees of the American Medical Association

At the formal opening of the new headquarters for the Lilly Research Laboratories, Indianapolis, on October 11, the following Fellows of the College were speakers Sir Frederick Banting, Toronto, Dr Elliott P Joslin, Boston, and Dr George R Minot, Boston

Dr David P Barr (Fellow), Busch professor of medicine, Washington University School of Medicine, St Louis, delivered a series of three lectures before the Honolulu County Medical Society, September 12 to 14. His titles were "The Pituitary Gland," "Hypoglycemia and Related Conditions" and "Parathyroid Gland and Calcium Metabolism"

Dr William B Castle (Fellow), Boston, Mass, gave the first Harvey lecture this year, October 18, at the New York Academy of Medicine, "The Etiology of Pernicious and Related Macrocytic Anemias"

The Philadelphia General Hospital, under the chairmanship of Dr Russell S Boles (Fellow), has inaugurated a series of Saturday morning clinics from 11 to 1 o'clock, covering a broad variety of medical and surgical subjects, with demonstration of cases, but without operative clinics. These clinics are conducted in the interests of the general practitioner and are open to the medical profession and to medical students. At the first clinics, October 6, Dr David Riesman (Fellow), Dr Thomas M McMillan (Fellow) discussed "Recognition of the Failing Heart," Dr Edward A Strecker (Fellow) presented a clinic on "The Neuroses as Encountered by the General Practitioner." On October 13, Dr Arthur C Morgan (Fellow) presented a clinic on "Physical Signs of Pulmonary Tuberculosis." On October 20, Dr Daniel J McCarthy (Fellow) presented a clinic on "The Cerebral Apoplexies." On October 27, Dr Robert G Torrey (Fellow) presented a clinic on "Rheumatic Heart Disease"

RESEARCH FELLOWSHIP OF THE AMERICAN COLLEGE OF PHYSICIANS

At a meeting of the Board of Regents at Chicago, Ill, April 15, 1934, the following resolution was adopted:

"Resolved, that the Board of Regents establish a Fellowship in the amount of \$1,800.00 to be known as the 'Research Fellowship of the American College of Physicians' and to be awarded each year on the recommendation of the Committee and the approval of the Board of Regents"

The Committee on Awards, appointed by the Board of Regents, is as follows:

David P Barr, St Louis, Chairman
Arthur R Elliott, Chicago
James H Means, Boston
William J Kerr, San Francisco
O H Perry Pepper, Philadelphia

The Committee proceeded immediately after the adoption of the resolution to obtain applications for this Fellowship. The names of a number of individuals applying for similar fellowships were obtained from the National Research Council, and from other sources. After reviewing these candidates' records and communicating with each, the names of two were selected by the Committee and presented to the Board of Regents of the American College of Physicians for final selection.

Dr Frederick Kellogg, of San Francisco, was awarded the Fellowship, and his work began on September 15. Dr Kellogg obtained his A B degree at Stanford University in 1927, and his degree in medicine at Harvard University Medical School in 1931. He then worked for a period of time with Dr Paul White, until he returned to California to take up clinical research work at the University of California Hospital. He has published a number of articles chiefly on cardiology and on anemia.

The problem Dr Kellogg intends to follow out during the coming year on the Fellowship of the American College of Physicians is a study of hemoglobin regeneration and the relative effectiveness of various dietary factors before and after gastrectomy. This work will be done in association with Dr Stacy R Mettier (Fellow). Dr Kellogg also hopes to pursue some work on phonocardiography with Dr William J Kerr (Fellow).

It is not too early to point out that this same Fellowship will be open again next year, and that applications may be filed at any time through the Executive Offices of the College.

FELLOWSHIP INSIGNIA FOR ACADEMIC GOWN

Occasional queries from manufacturers of academic gowns indicate some Fellows of the American College of Physicians are not familiar with the official method of indicating Fellowship or Mastership in academic dress.

There is no official gown for the American College of Physicians, but a special insignia to be attached to any regular or special gown a member may already have. For Fellowship, the insignia is a cross of the shape of that of the Key of the College, three inches in height, of green velvet, with the seal of the College stitched in solid gold braid, to be attached and worn on the right side of the academic gown. For Mastership, the insignia is a similar cross, except of gold cloth with green braid.

These insignia may be obtained, ready for stitching to the gown, through the Executive Offices of the College, 133-135 S 36th St, Philadelphia, Pa.

CIRCULATION OF ANNALS OF INTERNAL MEDICINE

In compliance with the regulations of the Code Authority for the Periodical Publishing and Printing Industry (A-3), the American College of Physicians, publishers of the ANNALS OF INTERNAL MEDICINE, presents the following statement concerning the circulation of said journal for the period beginning January, 1934, and ending June, 1934.

Average gross circulation —3,197

Average net paid circulation—3,074

Subscribed and sworn to by E. R. LOVELAND, Executive Secretary of the American College of Physicians, this eighth day of October, 1934.

My commission expires April 8, 1937
(SEAL)

B. M. SNOVER,
Notary Public

OBITUARIES

DR GEORGE WALTER HOLDEN

1866-1934

By the death of Dr George Walter Holden, of Denver, from coronary thrombosis on July 11, 1934, Colorado lost one of her ablest and best known physicians. Born in Barre, Mass., September 17, 1866, his early education was obtained in the Barre Academy, and in the Mount Herman Academy at Northfield, Mass. Following a business course Dr Holden's artistic nature craved a medical career and when he had saved enough money he entered the University of Vermont at the age of 26, graduating in medicine in 1895. After hospital experience in Boston a general practice was undertaken in North Brookfield, Mass. He was overtaken with pulmonary tuberculosis and came to Colorado where his fame was made as a specialist in that disease.

When Mr Lawrence C Phipps, former United States Senator from Colorado, conceived and built the Agnes Memorial Sanatorium for Tuberculosis, his family physician, Dr Holden, was appointed Superintendent and Medical Director, which position he held from 1904 to 1932 when the institution closed. While Dr Holden's ability as a well-trained physician was thoroughly tested in this long and faithful service, a marked administrative and disciplinarian capacity was developed which made the Agnes Memorial Sanatorium recognized as one of the best sanatoria in the country.

Dr Holden was a member of the American Clinical and Climatological Association, the American Hospital Association, the American Sanatorium Association, the American Public Health Association, the National Tuberculosis Association (Vice-President and Director), the Colorado Tuberculosis Association (President), the Denver Tuberculosis Society (President and Director), and the Colorado Hospital Association (Vice-President). Dr Holden was also a Fellow of the American Medical Association and of the American College of Physicians.

While not a frequent contributor to medical literature Dr Holden was interested in the investigation of such rare conditions as aspergillosis of the lungs. Dr Holden gave himself to such activities as the Child Research Council and possessed all the qualities of a true and earnest physician.

GERALD B WEBB, M D, F A C P,
Governor for Colorado

DR BENJAMIN GUTMANN

Dr Benjamin Gutmann (Fellow), 144 Livingston Avenue, New Brunswick, N J, died August 7, 1934, at the Middlesex Hospital after several months illness from bronchiogenic carcinoma.

Dr Gutmann was born at South Amboy, N J , December 29, 1877 He received his preliminary education from the schools of his native town and entered the Glenwood Military Academy, Matawan, N J , from which he graduated in 1893 He entered the Jefferson Medical College, Philadelphia, Pa , in 1893 and graduated in 1897 He returned to his native town, New Brunswick, and practiced general medicine until 1913 when he went abroad to study at Vienna and Berlin and returned again to resume his practice

In 1919 he did special work at Harvard University Graduate School and was at the Massachusetts General Hospital, Boston, and the Presbyterian Hospital, New York City Upon his return he limited his practice to Internal Medicine Dr Gutmann was Chief, Medical Service, Middlesex General Hospital, and St Peter's General Hospital, New Brunswick, at the time of his death

He was married to Marie Louise Fisher, daughter of Charles and Ella De Hart Fisher, November 15, 1904, and is survived by four daughters, Margaret, Elizabeth, Anne and Mrs Willard Potter

Dr Gutmann was a member of the Middlesex Medical Society, the New Jersey State Medical Society, the American Medical Association and a Fellow of the American College of Physicians since 1929 He was also a member of the Rutgers Medical Club, Anglo-American Society of Berlin, American Association of Vienna and the Academy of Medicine of Northern New Jersey

The profession and College have lost a worthy member

CLARENCE L ANDREWS, M D , F A C P ,
Governor for New Jersey

DR ISADORE D BRONFIN

1886-1934

Born in Russia in 1886, Dr Bronfin came to the United States in 1902 He was educated at the University of New York and graduated in medicine at the Long Island College Hospital in 1911 Developing pulmonary tuberculosis Dr Bronfin came to Colorado in 1920 and, as so many of his predecessors had done, took up the specialty of tuberculosis in which field he became a national authority Dr Bronfin became Superintendent of the Jewish Consumptive Relief Society and was appointed Medical Director of the National Jewish Hospital in 1927 Absorbed in his work and indefatigable in his efforts to help the tuberculous, his own affliction relapsed and his death occurred July 30, 1934, following a series of serious pulmonary hemorrhages Dr Bronfin was loved and respected by all the profession of Colorado He was a member of the faculty of the University of Colorado School of Medicine, and was a conscientious attendant of all medical society meetings Dr Bronfin is survived by his wife, Mrs Elizabeth Bronfin, and by two sons

GERALD B WEBB, M D , F A C P ,
Governor for Colorado

DR CURRAN POPE

Dr Curran Pope of Louisville, Kentucky, died September 21, 1934, at his home. He had been an Associate of the American College of Physicians since 1920. He was born in Louisville on November 12, 1866, and after graduating from public and high schools received his degree in Medicine from the University of Louisville Medical Department, 1889. He took postgraduate courses in New York, London, Paris, Vienna and Berlin, and became resident physician at the Central State Hospital in 1891. He was connected with the Hospital College of Medicine, the Louisville College of Medicine, Kentucky School of Medicine and the University of Louisville Medical Department during the years 1892 to 1910. He was very much interested in physiotherapy and, at the time of his death, was Director of the Pope Hospital in Louisville. He was a past President of the Ohio Valley Medical Association, Western Physical Therapy Association and the American College of Physical Therapy. He was the author of a book on "Practical Hydrotherapy" and several hundred articles and many editorials contributed to leading medical magazines of this country.

ARTERIOLAR INFARCTION *

By J C MEAKINS, M D , F A C P , *Montreal, Quebec, Canada*

FOR want of a better title I have chosen the above, to include the hemorrhages into the skin, mucous membranes and viscera which are of such common occurrence in those pathological states where hypertension is a prominent feature. It may be taken at the present time that hypertension as a functional disturbance is dependent upon an increased peripheral resistance in the vascular system. There is considerable difference of opinion as to whether this increased resistance is a function of the whole arteriovascular tree including arteries, arterioles and arterial capillaries, or whether it is principally produced by a narrowing of the arteriolar bed with normal pressure in the arterial capillaries. For the present this discussion need not enter into our consideration.

That the functional disturbance which produces hypertension is more or less constant throughout the body is usually agreed, with the qualification that there are periodic fluctuations in the total effect and also isolated variations in tissues and organs from time to time. The principal pathological states with which hypertension is intimately associated might be stated as follows: (1) eclampsia, (2) acute hemorrhagic Bright's disease, (3) hyperpiesia, and (4) chronic hemorrhagic Bright's disease with nephrosclerosis. I have listed them in this order as it corresponds to the acuteness with which the hypertension develops.

There is general agreement that the original disturbance is due to some vaso-pressor action on the arterial system and not to an anatomical disturbance. The latter, however, in the last two groups may occur in time, more as a consequence rather than a cause of the functional disturbance. The anatomical changes can be best described as a hypertrophy of the muscular elements of the cardiovascular system, as shown by the increased volume of the myocardium and muscular coats of the arteries and arterioles. There is also a thickening of the arterial intima with narrowing of the lumen which in time may lead to a gradual obliteration of the smallest arteries, and changes in the parenchymatous architectural patterns. These anatomical changes are as a rule a function of time and severity of the pressor effect.

* Read at the Chicago meeting of the American College of Physicians, April 16, 1934.
From the Department of Medicine, McGill University Clinic, Royal Victoria Hospital, Montreal.

These changes are more or less uniform throughout, in distinction to the true degenerative arteriosclerotic process which is irregular and patchy and in itself is not necessarily associated with hypertension and seldom if ever produces it

In the past, hemorrhages accompanying hypertension were attributed to various "toxic" causes or to anatomical changes, the result of arterial damage. At the present time opinion tends more to the conception that they are a direct result of the general or local variations in the hypertensive state. The condition of the smaller arteries, arterioles, capillaries, venules and smaller veins can be studied in life by experimental methods in the skin and fundus oculi.

We are indebted to Richer and his coworkers¹ for their experimental studies of the circulatory movements in normal and abnormal states. They clearly demonstrated that under moderate stimulation—mechanical, chemical or bacterial—the smallest arteries contract, slowing the blood flow through them, and the capillaries and venules dilate. If the stimulus be sufficiently intense the proximal arteries contract to such a degree as to pro-

FIG 1 Mesentery of a rabbit stimulated with a suspension of *B. coli*, showing contracted arteriole and dilated venule with diapedesis and hemorrhage

duce closure Richer has given the term *peristasis* to the slowing of the stream and *stasis* to its complete stoppage But the condition is not fixed and varying degrees may be observed, and stasis is usually preceded by an extreme slowing which has been termed *prestasis*

In the stage of *prestasis* there is an out-flowing of the blood constituents from the capillaries and venules, and, depending upon the degree of *peristasis*, there may be exudates of plasma, leukocytes or finally erythrocytes In the extreme slowing, blood extravasation by diapedesis occurs, in other words, hemorrhages through vessels which are not ruptured When stasis or complete stoppage occurs, tissue necrosis (infarction) ensues unless collaterals are available This permeability of the capillaries and venules is enhanced by the local oxygen want produced by the slow circulation, and is in proportion to the degree and duration of the *peristasis* The principal features to be seen are the narrowed small arteries and arterioles with dilated and engorged capillaries, venules and smaller veins about which masses and collars of erythrocytes are seen to appear rapidly The extent of the hemorrhagic extravasation may be extreme, extending over large areas and producing extensive local destruction (Figure 1)

In pathological states similar phenomena may be observed Koch,² in Volhard's clinic, showed that following scarlet fever irregular elevations in blood pressure occur several days before the onset of the classical symptoms of nephritis With the increase in blood pressure there is a generalized constriction of the small arteries and arterioles, which can be studied in the skin and the retina It is at this time that hemorrhages appear in the skin, mucous membranes, retina and kidneys and probably other viscera as discovered at post mortem

A lucid and illuminating review of the changes in the retina in hypertensive conditions has recently been published by Elwyn³ In this he explains and interprets all the changes found in the retina in so-called nephritic retinitis on the experimental work of Richer and his coworkers It is the only interpretation at the present time which in any way approaches all the requirements

In acute nephritis and eclampsia with hypertension, the fundal lesions are not necessarily progressive but are variable and labile, varying in degree from day to day and being subject to pronounced and sudden changes

The arterial constriction occurs also in the brain and is responsible for the edema and focal hemorrhages (figure 2) which give rise to the cerebral symptoms, convulsive seizures and associated phenomena

It has already been stated that hemorrhages are a common occurrence in the hypertensive state Postmortem examinations show that no organ or tissues may be exempt However, particular attention has been focused upon certain sites because of the conspicuous disabilities which may ensue Melena, hematemesis, hematuria and purpura, do not lead to grave disabilities comparable to those which are met with when hemorrhagic extravasations occur in the fundus oculi, brain, and myocardium

FIG 2 Microscopic section of the brain from a case of cerebral hemorrhage in a man aged 24 with hyperpiesia. It shows continuous perivascular "collar" hemorrhage with extensive erythrodiapedesis

FIG. 3 Microscopic section of the brain from a case of cerebral hemorrhage in a woman aged 31 with hypertension. It shows erythrodiapedesis surrounding a capillary and in the lower right corner a venule filled with agglutinated erythrocytes producing thrombosis with but little erythrodiapedesis.

Cerebral hemorrhage is usually conceived to be due to an actual rupture of a vessel, although in a search of the literature actual proof of such in all but a small percentage of cases is sadly lacking. In fact, the majority of evidence would indicate that such is not the case, and experimental evidence would strongly point to stasis and diapedesis as being the principal cause, particularly when hypertension is present. Indeed, Virchow was strongly in favor of this interpretation more than 75 years ago.

On analyzing cases of cerebral hemorrhage certain rather striking features are revealed. Over a period of five years, 37 cases of cerebral hemorrhage, exclusive of those with a syphilitic or traumatic history, have been analyzed. Three of these were cases of eclampsia, 23 had hypertension with a diastolic pressure of over 110 mm of mercury. The average systolic pressure was 224 mm, the average diastolic pressure, 130. Sixteen were males and seven females, and the average age was 48, the oldest being

FIG 4 Macroscopic section of brain from a young woman aged 22 with eclampsia and hypertension. It shows two gross and numerous minute hemorrhages.

62 years of age. The remaining 11 cases had a diastolic pressure of 90 mm of mercury, the average systolic pressure being 143 mm and the average diastolic being 78 mm. Eight were males and three females; the average age was 73 years (58 to 85). In the hypertensive group, hemorrhages varied from small petechial extravasations to mass and widely destructive lesions. Not only were they frequently multiple in the brain (figures 4 and 5), but hemorrhagic extravasations were always found in other viscera—such as the gall-bladder, stomach, duodenum, ileum, kidney (figure 6), renal pelvis, and bladder—if thoroughly examined. This was also true in the cases of eclampsia. In all of these hemorrhagic states in which detailed examinations of the fundi were recorded, retinitis was found. In the cases with low or normal blood pressure, hemorrhages were always isolated in the brain and were single. Visceral scarring suggestive of old vascular lesions was sometimes

FIG 2 Microscopic section of brain from a young woman aged 22 with eclampsia. It shows confluent hemorrhages.

In none of these cases was there retinitis, although all revealed arteriosclerosis of the retinal arteries without the so-called loss of compensation in the veins

The hemorrhagic extravasations in hyperpiesia and eclampsia are practically identical with those produced by local irritations, as was brilliantly investigated by Richer and his coworkers (figure 1) In the experimental states, if the stasis was complete, hemorrhagic extravasations did not occur, but agglutination of the erythrocytes occurred within the capillary or venule, leading to thrombosis (figure 3) This has also been demonstrable in cases of hyperpiesia and eclampsia Anatomical occlusion of an artery or arteriole, due to a degenerative arteriosclerosis, may also produce complete stasis and thrombosis or rupture of such a vessel may occur, but, as already pointed out, this is usually a local lesion, although repeated accidents may occur There is not, however, the labile, fluctuating, systemic disturbance present which is so characteristic of the functional hypertensive states

FIG 5 Microscopic section of the same brain as in figure 4 through the area with minute hemorrhages It shows two of such and extensive erythro-diapedesis elsewhere

FIG 6 Microscopic section of the kidney in a case of eclampsia (same as in figure 4) It shows dilatation and engorgement of the arterioles with extensive erythro-diapedesis into the surrounding parenchyma

The use of the term "hemorrhage" when hypertension is present is not as expressive as "infarct" in the true sense of the word, as it is derived from the Latin "infarcire" meaning to stuff. The hemorrhagic extravasations in those conditions with associated hypertension seem undoubtedly to be due to vasoconstriction leading to slowing of the blood stream or peristasis, and then more or less extensive diapedesis of the erythrocytes into the surrounding tissues.

I wish to express my thanks to Dr W H Chase for permission to use the microscopic slide for figure 1, and for his generous help in the preparation of the pathological material.

THE CLINICAL IMPLICATIONS OF THE THYMUS AND STATUS THYMICO-LYMPHATICUS^{*}

By A GRAEME MITCHELL, M D, F A C P, and ESTELLE W BROWN, B S,
Cincinnati, Ohio

OPINIONS concerning the clinical disturbances attributable to the thymus—to employ the metaphor of the pendulum—have swung from one end of the arc to the other, and the organ has been incriminated on the one hand as the cause of many symptoms, and on the other has been considered as relatively innocent and inoffensive. The truth of the matter probably lies somewhere between these two extremes, although it is not easy to know just where to arrest the pendulum. Confusion is increased by the fact that certain physicians, whose convictions must be received with respect, have expressed extreme views, sometimes doubting that the thymus ever causes manifestations which are clinically evident. Furthermore, much of the literature on this subject is cluttered with personal opinions and enthusiasm, unsubstantiated by facts, or, worse, based upon erroneous assumptions concerning the anatomic features of the thymus or unwarranted presumptions in regard to its functions and pathologic physiology.

Since this presentation is confined to the clinical aspect of the thymus in infancy and childhood much controversial matter may be eliminated.

One can approach the problem by propounding certain queries, the answers to which would be of great assistance to the clinician. Since the solution of these questions is not yet available, much discrimination must be employed in separating speculation from fact. It is this that we are attempting from the viewpoint of the physician who is frequently faced with the interpretation of symptoms and the indications for treatment.

What are the symptoms which could be caused by enlargement or disorders of the thymus gland? Put more specifically. Can enlargement of this structure cause dyspnea, crowing respiration, cough and cyanosis, and can disturbance in its function be a factor in convulsions and sudden death, or lead to such conditions as pylorospasm?

The anatomic relations of the thymus must be considered. In early life it occupies a position in the lower anterior portion of the neck and extends behind the upper part of the sternum. It is attached to and overlies the upper part of the pericardium and is in intimate contact with the left innominate vein, the superior and inferior vena cava, the pulmonary artery, and with the vagus, phrenic and recurrent laryngeal nerves. The size of the thymus at different ages has been a source of great confusion, largely because observations were on pathologic subjects. It has, however, been demonstrated,

^{*} Read at the Chicago meeting of the American College of Physicians April 20, 1934.

College of Medicine, University of Cincinnati.

particularly by Boyd,¹ that the weight and dimensions of the organ are dependent to a great extent upon the general nutritional state of the body, so that in a poorly nourished or dehydrated child it may be only one-half or one-third of the size it possesses in a well nourished child of the same age. With certain illnesses, its tissue may decidedly diminish, even though there is relatively little loss in general body weight. Of some importance is the fact that there is a decided temporary decrease in the weight of the thymus from birth to about two weeks of age. With this exception, however, it should be noted that, while it increases in weight until about the age of puberty, its size in relation to total body weight is decreasing.

Many authors have denied the possibility of even a greatly enlarged thymus, relatively soft organ that it is, causing compression of a stiff, cartilaginous trachea. It has been claimed, for example, that it requires a weight of about 1000 grams to close the trachea of an infant. Such observations are interesting, but there is no proof that an enlarged thymus during life might not exert such a pressure. It is held by some clinicians that any swelling of the thymus would follow the path of least resistance, and expansion would take place laterally rather than in the antero-posterior direction in which tracheal compression would be brought about. There is, nevertheless, no proof that there is less resistance in the neck or in the thorax to expansion in a lateral direction than in an antero-posterior one, and it is to be noted that the chief danger from compression of the trachea would be in the bony and rigid thoracic inlet, where there is relatively little chance for expansion in any direction.

Can the thymus actually compress the trachea, and what is the evidence for this? Necropsy studies of this problem can be criticized because distortion of antemortem conditions might take place, and edema and congestion of the thymus, which may have been the active factors, disappear after death. The most direct evidence would be visual demonstration during life. Jackson, quoted by Pancoast,² has claimed to have seen tracheal compression by the thymus by means of the bronchoscope in over 300 patients who had obstructive symptoms as wheezing, dyspnea, and impending asphyxia. Pancoast and others have apparently demonstrated roentgenologically that the thymus actually can cause compression of the trachea. Additional support that compression occurs might be adduced from the clinical observation that thymectomy and the reduction in size following radiologic treatment of the thymus cause cessation of obstructive symptoms. The fact that symptoms which could be attributed to thymic pressure appear largely in the first year of life is of interest in this connection, since, while increasing in size after that time, the thymus is not growing at the same rate as the chest, and, therefore, becomes relatively incapable of causing pressure.

As already noted, the trachea is not the only structure with which the thymus is in contact. For example, in the bony thoracic inlet the laryngeal nerves might be compressed by a turgid or hyperplastic thymus, and the unilateral or bilateral paresis or paralysis of the vocal cords, resulting

from this might be a cause of such symptoms as noisy breathing, stridor, brassy cough, or, it is claimed, in some instances of death. Pressure on other nerves is unlikely. On the possibility of pressure upon the great vessels with reduction of their lumen and resultant cyanosis, there may be cited the work of Noback,³ from which he concluded that an increase in the antero-posterior extent of the thymus could compress these structures, and that in some of the cases studied at necropsy this had evidently occurred. The esophagus may apparently also be compressed, and this would account for the difficulty in swallowing already mentioned. Cyanosis of the head, neck and upper extremities has been described as a rare accompaniment of enlarged thymus. It could be explained by pressure on the left innominate vein, and that this can actually occur is indicated by one of Noback's dissections.

Much that is stated concerning the functions and physiology of the thymus is the result of speculation and rests upon hypothesis only. The methods of study have varied widely and include observation of histologic structure, of the supposed results of enlargement, of the effects of extirpation and of experiments with feeding or injecting extracts of the gland. Even if time permitted it would be presumptuous on my part to analyze critically these studies, when the most careful and earnest observers often disagree both in results and interpretation. It is easy to point out, however, that histologic structure is difficult to correlate with function, that extirpation of the thymus in animals, or the feeding, injection or implantation of it, does not necessarily indicate that a similar effect would be observed in man, that any after-effect from excessive radiation of the thymus has not been convincingly demonstrated, that, while there may be synergy of the thymus with certain organs of internal secretion, particularly the adrenals, further study is required to conclusively demonstrate this fact. None of this is to say that the thymus is functionless or physiologically inactive, but rather that there is so much uncertainty with regard to this structure that the physician is forced to solve his clinical problems without the assistance that more accurate knowledge would give him.

In the attempt to evaluate the significance of some of these symptoms in their relation to enlarged thymus we have studied a group of 197 infants and children in whom roentgenologic examination had been made, of these, 116 had thymic shadows greater than normal, and 81 did not. The latter group was secured largely by routine roentgenograms of the thymus taken on cleft palate and hare-lip cases. The value of roentgenograms in the diagnosis of enlargement of the thymus will be discussed later.

By means of the four-fold table an analysis was made of the entire group of 197 patients, when they were divided into four mutually exclusive groups as follows

- (a) 80 with enlarged thymus and symptoms (convulsions, dyspnea, including suffocative attacks, crowing respiration, cough, cyanosis, pylorospasm, sudden death),

- (b) 36 with enlarged thymus but without the foregoing symptoms,
- (c) 43 with no enlargement of the thymus but having the foregoing symptoms,
- (d) 38 with no enlargement of the thymus and without the foregoing symptoms

The object was to ascertain whether the symptoms were significantly associated with an enlarged thymus gland. The χ^2 was 2.26. The mathematical implication is that all four groups came from the same universe, i.e., that the symptoms considered are not inevitably associated with enlarged thymus. Such would be the conclusion from a clinical point of view, but it is interesting that this can be supported by mathematical analysis.

If, however, these 197 patients are divided into two groups according to the presence or absence of enlarged thymus (see table 1), it is seen that

TABLE I
197 Infants and Children

| | No Symptoms | Con- vul- sions | Dysp- nea | Cya- nosis | Crow- ing Resp | Cough | Pyloro- spasm | Sudden Death | Total Symptoms |
|-------------------------|----------------|-----------------------|--------------|---------------|----------------------|-------|------------------|-----------------|-------------------|

| Thymus Not Enlarged, 81 | 38 | 2 | 10 | 12 | 0 | 7 | 33 | 1 | 43 |

of the 116 children with enlarged thymus gland, 80 (69 per cent) had symptoms. Contrasted with this group is another of 81 children who did not have enlarged thymus glands, yet 43 (53 per cent) of these had symptoms similar to the former group. When these groups are analyzed according to the Chi-square test, χ^2 is 6.39, showing that these two groups are not from the same universe. Further analysis of the rate of incidence of the various symptoms shows that most of these are more apt to be associated with enlarged thymus than with one of normal size according to the roentgenogram.

It should be stated that in the 80 patients with enlarged thymus glands and symptoms, there were complicating conditions in 56 (70 per cent) which might have been responsible for these symptoms. In an attempt to evaluate these factors a further Chi-square test was done, using as the universe only those 80 patients who had an enlarged thymus, and subdividing this universe into two groups (table 2) as follows:

- (a) 24 patients who had symptoms but in whom it was impossible to attribute these to any other cause than enlarged thymus, and
- (b) 56 patients* who had symptoms which might equally well have been at-

* These 56 patients, in addition to enlarged thymus had other conditions as follows: Infections of the upper or lower respiratory tract in 20 instances, increased intracranial pressure in 11, congenital heart disease in 6, pylorospasm in 6 (included in this group since there were no other symptoms than pylorospasm), spasmophilia in 3, pulmonary atelectasis

TABLE II
80 Patients with Enlarged Thymus

|---|-----------------------|--------------|---------------|----------------------|-------|------------------|-----------------|
| Symptoms Due to Enlarged Thymus, 24 | 5 | 6 | 10 | 4 | 5 | 12 | 3 |
| Symptoms Possibly Due to Some Other Cause, 56 | 16 | 28 | 22 | 6 | 17 | 4 | 4 |

tributable to some other cause or disease condition present in the patient at the time

It was shown that these two groups also came from different universes, the sigma ⁴ being 4.47. The rate of incidence of symptoms was higher in those patients with an enlarged thymus gland who had other reasons for these symptoms, the exceptions being only sudden death and pylorospasm. (The latter could be explained by the fact that all cases of pylorospasm were included in the "pure" thymus group unless shown by operation to be true pyloric stenosis.) The implication here is that a child with an enlarged thymus gland and some complicating factor, as respiratory infection, is more liable to have symptoms than a child with an enlarged thymus gland only, and this would be logical from a clinical viewpoint. It should be stated, however, that the mathematical analysis was complicated by the fact that the symptoms were not mutually exclusive, and it is obvious that all of the symptoms are such that an enlarged thymus is not necessary in their production.

The interesting association of enlarged thymus with pylorospasm has been described by a number of authors, who have brought forward as explanation the theory that the pylorospasm and the enlarged thymus are both dependent upon vagotonia, the result of insufficient adrenalin production. Of our 116 patients who had an enlarged thymus 20 had symptoms of pylorospasm, and of our 81 patients who did not have an enlarged thymus 33 had symptoms of pylorospasm (see table 1). When the rate of incidence is considered it is seen that, since the rate is more than twice as great (33/81) in the negative thymus group as in the positive thymus group (20/116) there is obviously no significant association between pylorospasm and enlarged thymus.

Is there such a condition as status thymico-lymphaticus or lymphatism?

The chief manifestation attributed to this diathesis is sudden death occurring without obvious cause, during anesthesia, or following such supposed factors as hypodermic injection, the administration of diphtheria antitoxin or of nonprotein material or drugs, chilling, extraction of teeth, fracture of the jaw, acrodynia in 2, enlarged bronchial glands in 2, esophageal atresia in 1, snuffles from syphilis in 1, muscarin poisoning in 1, asthma in 1. The various symptoms analyzed, such as convulsions, dyspnea, cyanosis and the like, present in these children could, as stated, equally well have been attributable to such conditions rather than to an enlarged thymus.

tures, psychic shock and the like. In the conception of status thymico-lymphaticus it is not necessary to believe that death or other symptoms are due to pressure of an enlarged thymus—in fact, some of the most ardent advocates of the existence of “lymphatism” find it difficult to assume this explanation. When the thymus is enlarged this is considered only a secondary phenomenon. In many studies there has been discovered no constant enlargement of the thymus in sudden death from unexplained causes.

In our present series of cases there were eight instances in which sudden death had been thought to be due to status thymico-lymphaticus. By roentgenograms or necropsy the thymus was found to be enlarged in seven. In three cases, two of which were studied by necropsy and enlarged lymphatic structures discovered, there was no factor found to account for death other than a possible status thymico-lymphaticus. Of the remaining five, necropsy showed in two congenital heart lesions, in one there was esophageal atresia, in one there was found at necropsy a cystic type of degeneration of the internal capsule, and in one, death had probably been due to muscarin poisoning.

It would appear to be fair to state that sudden death occurs in some cases in which it cannot be attributed to any well defined cause, but in which there is found hypertrophy of the lymphoid structures throughout the body, and at times a hypertrophied thymus gland. Further study may perhaps show that this is associated with disturbed function of the thymus, or more likely that the so-called thymico-lymphaticus is a secondary or related manifestation of some other alteration of body equilibrium.

Many of the explanations given for sudden death in status thymico-lymphaticus, as the effect of an unknown toxin, “hyperthymization,” “lymphotoxemia,” vagotonia, deficiency of the chromaffin system, and allergic reaction, are resounding in terminology but have little or nothing to uphold them. The theory of adrenal deficiency, however, has much in its favor, and is supported by certain physiologic and pharmacologic facts, a discussion of which lies outside the province of this presentation. Adrenal insufficiency seems to be a possible explanation of certain cases of sudden death which can be accounted for in no other way. What this has to do with the thymus is another matter, although there may be an associated thymic and lymphoid hyperplasia, and it is interesting that in adrenalectomized animals there follows hypertrophy of the thymus. That cerebral hemorrhage is sometimes a cause of sudden death in children with enlarged thymus glands and lymphoid hypertrophy is undoubtedly true, and we have seen at least two such cases in which histologically there appeared to be thin-walled blood vessels and also small hearts. Cerebral hemorrhage, however, could account for only a relatively few instances of sudden death. Infrequent, too, is “thymic apoplexy” in which there is extensive hemorrhage into the thymus gland. This condition is, at any rate, probably associated with syphilis, and if so, does not belong in the category of ordinary thymic hyperplasia or status thymico-lymphaticus.

How is the clinician to diagnose thymic enlargement and status thymico-lymphaticus?

It does not appear correct to discard entirely the possibility of the effect of pressure by the thymus. It should be one of the causes to be investigated in dyspnea, stridor, crowing respiration and cyanosis, and perhaps also in other symptoms such as brassy cough, suffocative attacks and the like. Percussion is of little value in outlining the lateral dimensions of the thymus, and the interpretation of it difficult unless the organ be greatly enlarged. Even if an increased area of dullness is found over the manubrium, this by no means eliminates the possibility that other intrathoracic structures may be responsible for it. Furthermore, it is quite likely that increase in the antero-posterior diameter of the thymus—a situation impossible to elicit by percussion—may be more important than lateral expansion of it. Increase of obstructive symptoms produced by flexion of the head, a procedure emphasized by some, does not differentiate thymic pressure from other causes of obstruction.

In regard to the diagnosis of status thymico-lymphaticus, little more can be stated than has already been mentioned. It would be difficult indeed to detail the diagnostic aids for a condition the pathogenesis of which is so little understood, and the very existence of which is denied by many. More and more reports indicate that careful postmortem examination would eliminate from the category of "thymus deaths" many cases formerly so classified. The weight of recent evidence, too, as already stated, whether obtained by anatomic or roentgenologic study, is against any correlation between undue oversize of the thymus and sudden death.

The merits of the demonstration of thymic enlargement on the roentgenogram must depend upon a correct evaluation of the size, shape and position of the organ in normal infants, and in addition the effect produced by respiration and the position of the patient. Most clinicians would agree that roentgenograms taken casually and only during one phase of respiration furnish little information concerning the size of the thymus. More work is needed to establish average boundaries, and this is rendered difficult by the fact that the normal size of the organ at any age in infancy or childhood is decidedly variable, and also that there are racial and geographic differences. That is to say, it cannot be stated that a shadow greater than a certain width is necessarily indicative of thymus enlargement, nor that it proves that obstructive symptoms are due to this. In fact, the roentgenogram may not infrequently disclose a greatly enlarged thymus when no symptoms are present. Probably something can be learned from lateral views concerning compression of the trachea. Perhaps it is fair to state that clinical symptoms are of as much, if not more value in the diagnosis of thymic pressure than are roentgenograms, unless the latter are taken and interpreted by experts with experience.

A few authors have claimed to have found considerable value in the fluoroscope in the visualization of the thymus and its compression of the trachea.

It would probably be a safe procedure to consider the possibility of thymic pressure in all cases of asphyxia, stridor, wheezing, brassy cough and cyanosis in infants, but to realize that it is a relatively infrequent cause of these symptoms. After the period of infancy, tracheal obstruction is still less apt to be caused by the thymus. It is always well to remember, too, that a moderate enlargement of the thymus might be a factor in adding to pressure produced by some other means. For example, an infant with an upper and lower respiratory infection might be further embarrassed in respiratory effort by an enlarged thymus which previously or subsequently would exert no effect. On the contrary, a presumably enlarged thymic shadow in an infant with obstructive symptoms should not be accepted as diagnostic and entirely explanatory of the symptoms, search must always be made for other possible causes of pressure.

We would like to emphasize the necessity for search for intrinsic and extrinsic sources of tracheal compression by palpation or inspection of the throat or by the use of the laryngoscope, bronchoscope or roentgenogram. The type of stridor is usually of little diagnostic value, and it has been our experience to see mistaken for thymic obstruction such conditions as foreign bodies, pulmonary atelectasis, lingual tumors, retropharyngeal abscess, stenosis of the larynx, abductor paralysis, papilloma of the larynx, and diphtheritic and other forms of laryngitis and tracheitis. Asthma, which may occur even in infancy, has been confused with thymic asthma. The danger of incorrect diagnoses in the conditions mentioned is obvious, since many of them are curable if recognized early, but may proceed to the necropsy table if the symptoms have too long been attributed to the thymus.

Convulsions not explicable on an organic or toxic basis should, in early life, lead to a suspicion of spasmodophilia rather than to a diagnosis of thymic disturbance.

Paralysis of the recurrent laryngeal nerve might in rare instances be due to thymic pressure. Cyanosis may be an accompaniment of many of the previously mentioned causes of respiratory symptoms, but in early life it is more frequently caused by congenital heart disease and pulmonary atelectasis or other pulmonary lesions than by laryngeal obstruction.

SUMMARY

Mathematical study has been carried out on a group of 116 infants and children who, according to roentgenograms, had an enlarged thymus, using as a control group 81 infants and children who did not have an enlarged thymus by the same criterion. Clinical impressions previously held were strengthened by the analysis. It would appear that certain statements can be made with reasonable assurance.

- 1 In some instances an enlarged thymus gland can cause pressure upon structures in the thoracic inlet and lead to the development of such symptoms as dyspnea, suffocative attacks, crowing respiration, cough and cyanosis.

- 2 The symptoms mentioned occur with many other diseases and ab-

normal conditions and these are perhaps more frequent causes of all of them than is enlarged thymus

3 An infant or child who has some cause for dyspnea, cough and cyanosis, as respiratory tract infection, congenital heart disease and the like, and who also has an enlarged thymus is more liable to develop these symptoms. Probably an enlarged thymus may aid in their production, even in such instances where in itself it would be insufficient to cause symptoms

4 From a mathematical point of view there is no significant association between enlarged thymus and pylorospasm

5 There is no proof that convulsions are associated with enlarged thymus, and their presence even in a patient with an enlarged thymus gland should lead to a suspicion that increased intracranial pressure, spasmophilia (tetany) or some other cause exists

6 An enlarged thymus according to roentgenograms is by no means necessarily associated with symptoms

7 Even when obstructive symptoms are present in an infant or child with an enlarged thymus, search must be made for other possible causes

8 This study furnishes no solution to the question of the relation of sudden death, not explicable by some discoverable cause, to status thymico-lymphaticus

THE CLINICAL MANIFESTATIONS OF AMYLOIDOSIS*

By MILTON B ROSENBLATT, M D , *New York, N Y*

THE recent widespread use of the Congo Red test for the clinical determination of amyloidosis has aroused much interest in a subject which for the past two or three decades had been looked upon more as a pathological curiosity than as a clinical entity. The favorable results originally submitted by Bennhold¹ 10 years ago have been repeatedly confirmed by other observers. Bookman and Rosenthal,² Schonberger and Rosenblatt,³ Nemeth,⁴ Shapiro,⁵ Wallace,⁶ and many others have reported corroborative evidence of the diagnostic value of the test. The observation by Bennhold, and others, that in certain nephrotic states there was an escape of the dye by way of the urine thus giving false readings was originally thought to be an important limitation, but subsequent quantitative studies have shown that the amount of the dye eliminated this way is too small to appreciably alter the determinations. Barker and Snell⁷ found that the largest amount of dye which had escaped by way of the urine in the course of any experiment did not exceed 2 per cent. In general, all who have worked extensively with the Congo Red test have found it an accurate procedure for ascertaining the presence of amyloidosis and agree with Rudolph⁸ that the examination produces no ill effects and that the percentage of error is very small. With minor variations, the criteria for interpretation established by Bennhold are still generally accepted. A positive diagnosis of amyloidosis should not be made unless over 50 per cent of the dye has been retained by the tissues in one hour. Because of this ability to make a definite premortem diagnosis there has been established a greater appreciation of amyloid disease as a clinical syndrome.

At the present time, even in large general hospitals, amyloidosis is encountered only on rare occasions. In a recent report from the Massachusetts General Hospital, Mallory⁹ stated that he had seen but four cases in six years. With the exception of tuberculosis institutions, similar conditions prevail everywhere. This low incidence, as compared with its common occurrence during the past century, has been attributed to surgical progress in the eradication of suppurative foci. It is difficult to state exactly how prevalent amyloidosis was during the nineteenth century but even before Virchow gave this form of degeneration its present erroneous name, lardaceous disease was a well known entity among English physicians. Probably the first description of amyloid disease in the literature was that of Hodgkin's¹⁰ in 1832, and many of the cases reported by Bright were really of lardaceous origin.¹¹ In 1854, Sanders¹² stated that waxy degeneration of

From the Tuberculosis Division of the Montefiore Hospital, Dr Maurice Fishberg, Chief of Division

the spleen, liver, and kidneys occurred in 10 per cent of all the necropsies at the Edinburgh Royal Infirmary Dickinson¹³ encountered 201 cases among the autopsies at the St George's Hospital between the years 1867 and 1894 but did not state what percentage of the total number the amyloid cases constituted Fagge¹⁴ found 244 instances at Guy's Hospital over a 21 year period From various other sources the impression is obtained that amyloidosis was a fairly common occurrence during the past century but it was stated by Leube¹⁵ that its incidence varied greatly in different localities even though the predisposing diseases might be equally prevalent

As was mentioned previously, very few clinicians have had the opportunity of studying large series of cases during the past 20 or 30 years Saleeby,¹⁶ in a series of 3047 consecutive necropsies at the Philadelphia General Hospital, found 50 instances of renal amyloidosis (17 per cent) which was approximately the total number of all the amyloid cases Waldenstrom¹⁷ observed 28 cases in 12 years Rosenblatt,¹⁸ in a series of 1727 consecutive necropsies at the Montefiore Hospital, found the incidence of amyloidosis to be 72 per cent Further analysis of these statistics reveals that tuberculosis has been by far the greatest etiologic factor in the production of amyloid degeneration and that, at the present time, it is the only factor of any significance In 504 cases at Guy's Hospital, cited by Herringham,¹⁹ it was the underlying disease in 37 per cent, in 430 cases at Edinburgh, collected by Gibson,²⁰ it was the etiologic agent in 45 per cent, and in Dickinson's series in 48 per cent Coming down to the present time its incidence is found still higher Saleeby found it the causative agent in 82 per cent, Waldenstrom in 93 per cent, and Rosenblatt in 88 per cent It is interesting to note that in the latter's report the incidence of amyloidosis among the tuberculosis patients was 244 per cent as contrasted with 12 among the patients with other types of chronic disease In the tuberculosis cases with suppurative complications such as pyothorax, or draining sinuses, the incidence was 352 per cent Fishberg,²¹ in his series, found that 44 per cent of the tuberculosis patients with suppuration had amyloid changes

It has been generally accepted by all writers on the subject that suppuration is the basic requirement for the development of amyloidosis It has also been stated that the only reason that tuberculosis, or any other systemic disease, can cause amyloid degeneration is through the intermediary of pus formation This contention has been well corroborated by statistical studies but it should also be realized that the absence of suppuration does not preclude a diagnosis of amyloidosis There was no evidence of pus formation in 17 per cent of Dickinson's cases and none in 60 per cent of the non-tuberculous and 29 per cent of the tuberculous cases in Rosenblatt's series Many other cases of amyloidosis without suppuration were reported by Bannick,²² Cabot,²³ Bannick and Barker,²⁴ Christian,²⁵ and others In addition to tuberculosis and local suppurative lesions amyloidosis has been found associated with almost every type of disease process including syphilis, leukemia, arthritis, multiple myelomata, cancer, bronchiectasis, pneumoconiosis,

osis, Hodgkin's, lymphosarcoma, and rheumatic heart disease. The high degree of tuberculosis incidence is in all probability due to the fact that it is one of the few diseases in which extensive tissue destruction and chronicity are combined, rather than to any peculiar relationship between the tubercle bacillus and amyloid. Syphilis which was formerly considered a very important cause of amyloidosis—most authors placed it next in frequency to tuberculosis—is now a very small factor. Bell²⁶ found it to be the underlying disease in four out of 65 instances, Rosenblatt in one out of 125, and Saleeby in none. This change has probably been brought about by the introduction of the Wassermann test and arsphenamine therapy. There have been recorded many instances in which even after necropsy there was disclosed no basic process to account for the development of the amyloid. These cases have been designated as idiopathic, or primary, amyloidosis and were described as early as 1856 by Wilks.²⁷

Inasmuch as the major etiologic agent in amyloidosis is a disease of young adults, amyloidosis occurs mainly in this age group. Most cases are found between the ages of 20 and 40 years but the disease has been reported in children as young as four years and in adults as old as 68. Sex is apparently no factor. It is practically impossible to determine accurately the time required for the development of amyloidosis because of the paucity of early manifestations. Waldenstrom¹⁷ observed that the onset of clinical amyloidosis usually occurred within one to two years after the appearance of the suppurative lesion. In Whitbeck's²⁸ series of bone tuberculosis cases the duration in each instance was at least two years. In Walker's²⁹ case of empyema, definite signs of amyloidosis occurred two years after the onset. At the Montefiore Hospital many cases of pulmonary tuberculosis were observed in which the clinical duration of the disease did not exceed two years and in which extensive amyloid disease was present on postmortem examination. It is unusual for amyloidosis to occur when the basic process is of less than one year's duration but exceptions have been noted. Dixon³⁰ reported eight cases with clinical history of less than one year, and eight of less than six months. Fagge³¹ discovered one instance of three months' duration following fracture of the spine, and Dickinson³² one of three weeks' duration following compound fracture of the lower extremity.

Amyloid degeneration has been found in almost every organ of the body—heart, lungs, trachea, liver, larynx, spleen, skin, tongue, adrenal, thyroid, kidney, pancreas, intestine, lymph node, parathyroid, diaphragm, seminal vesicles, conjunctiva, bladder, and even brain. However, most of these organs are seldom involved and some of them only in isolated instances. The clinical syndrome of generalized amyloidosis is produced by involvement of the liver, kidney, and spleen. There is some variation among different reports as to which of these organs is most frequently affected but there is general agreement that all three are simultaneously involved in at least 60 per cent of the instances. The spleen is often involved alone, the kidneys seldom, and the liver rarely. Next in importance to these

organs is the adrenal which is usually implicated in association with the other three. The clinical course of amyloid disease depends on the extent of degeneration of these organs. The one exception to this is the heart, extensive involvement of which produces myocardial insufficiency and a clinical picture which is entirely one of cardiac decompensation. The amyloid in these instances is usually confined to this organ. Such cases are exceedingly uncommon and are obviously most difficult to diagnose during life. A few instances have been recorded by Wild,³³ Steinhaus,³⁴ Beneke and Bonning,³⁵ Kann,³⁶ Lubarsch,³⁷ Larsen,³⁸ and Warren.³⁹

The constitutional symptoms associated with amyloidosis such as pallor, anemia, weakness, and cachexia are so interwoven with the underlying disease that it is inadvisable to consider them of diagnostic value. While it is true that many cases do have a typical waxy facies this is by no means a universal finding and its absence is of no importance. The distinguishing symptoms and signs of amyloid disease are the clinical manifestations of the degenerative process as it affects each particular organ. The extent of the physiologic changes produced by amyloid varies greatly among the different organs so that the clinical features of each case depend on the organs involved and the degree of involvement. This explains why so many instances are discovered only after postmortem examination. In Dickinson's⁴⁰ series 27 per cent of the cases presented no symptoms or signs.

Of the organs of major importance in amyloidosis the spleen is implicated the greatest number of times. In a study of 5000 consecutive necropsies Krumbhaar⁴¹ found 156 instances of splenic amyloidosis as compared with 83 of hepatic and 78 of renal involvement. Parkes⁴² found the spleen implicated in every instance of amyloid disease. Despite this high incidence, splenic amyloidosis produces practically no symptoms other than the sensation of having an enlarged organ in the abdomen, and extreme enlargements are unusual. Inasmuch as most of the patients are bedridden because of the underlying disease, the disturbances noted in other splenomegalies such as dragging feeling and pressure on the surrounding organs are usually absent. The amyloid spleen when palpable is felt as a hard and non-tender mass. Splenic amyloidosis produces no manifestations of splenic insufficiency and there has been no evidence reported that it in any way alters either the clinical course or the prognosis. Amyloidosis of the spleen presents no distinguishing features of diagnostic value.

Because of its size the liver shows the greatest amount of amyloid change and it is implicated in about 60 per cent of the cases. The large quantity of amyloid substance found in the liver on necropsy as compared with that in the other organs has given rise to the suggestion that it is the amyloid of the liver which produces retention of the Congo Red during performance of the test. Bookman and Rosenthal² state that a positive test is not obtained unless the liver is involved. This observation has been found generally correct but exceptions have been noted.¹⁸ The liver, like the spleen, also produces few symptoms. It is usually found enlarged and occasionally

extends into the pelvis. On palpation it is firm, smooth, and not tender. There have been few studies on the effect of amyloidosis on hepatic function. Such observations as have been recorded indicate that even the most extensive amyloidosis produces no impairment. According to Parkes⁴² icterus is never caused by amyloid of the liver and in those rare instances in which both icterus and hepatic amyloidosis co-exist it is not difficult to ascribe another cause for the jaundice. Dickinson⁴⁰ found one instance of jaundice among 65 amyloid livers and in this case there was also present an hydatid abscess. The writer has studied over a hundred cases of amyloidosis of the liver without encountering a single instance of jaundice. In two cases in which the bromsulphthalein test had been performed, Bannick²² found negative results. With regard to both liver and spleen there is a marked disproportion between the degree of involvement and the symptoms produced.

Most patients with generalized amyloidosis show signs of asthenia, hypotension, and failure of the peripheral circulation. Although adrenal amyloidosis has been found to occur in as much as 40 per cent of the cases¹⁸ these symptoms are to be interpreted as part of the syndrome of the basic disease rather than as due to adrenal failure. Inasmuch as Addison's disease is itself very uncommon it naturally follows that adrenal insufficiency due to amyloidosis must be exceedingly rare. However, a few authentic cases have been reported. In a series of 2550 necropsies, Philpott⁴³ found 14 cases of Addison's disease one of which was due to amyloidosis. Hunter and Rush⁴⁴ reported a case in a young adult with pulmonary tuberculosis and generalized amyloidosis. McCutcheon⁴⁵ described an instance in a patient with hypernephroma, and other individual cases were reported by Bitorf,⁴⁶ Schultz⁴⁷ and Schlesinger.¹⁸ It is to be emphasized that these citations represent the approximate total number of cases in the literature and that, in the usual course of events, amyloidosis of the adrenals produces no characteristic clinical features. Adrenal insufficiency due to amyloidosis was not observed in any of the large series of cases reported.

Ever since amyloidosis has been studied clinically it has been realized that the significant features are those produced by involvement of the kidneys. Of 86 cases which presented signs in Dickinson's⁴⁰ series, 76 were renal in origin. The most common sign of renal amyloidosis is albuminuria, particularly progressive albuminuria. This was noted in 90 per cent of Dickinson's cases, in 72 per cent of Saleeby's¹⁶ cases, and in 92 per cent of Dixon's³⁰ cases. In a patient suspected of amyloidosis, albuminuria which cannot be ascribed to any other cause is an important diagnostic consideration. However, the absence of albuminuria does not rule out renal involvement and many such instances have been reported. Waldenstrom¹⁷ states that even extensive amyloidosis may be present without albuminuria but, as has been pointed out by Leube,⁴⁹ these cases are to be considered as exceptions. The amount of albumin present in the urine is usually considerable, but the actual quantity varies greatly among patients. Most cases do not

exceed 10 grams daily even when the amyloid is very extensive, but Bartels⁵⁰ observed one with 32 grams. The average ranges between 2 and 5 grams. Bartels noted the presence of large amounts of globulin in the urine and thought that this finding might be of diagnostic import. Joachim⁵¹ described a low albumin-globulin ratio in the urine as did also Hiller⁵² who stressed this point as a differential between amyloid and other types of nephrosis. Although polyuria has been mentioned as a significant finding by Floyd,⁵³ Todd and Sanford,⁵⁴ and others it is a very variable occurrence and is probably associated more with disturbed renal function terminally than with any peculiarities of amyloid degeneration. Urinary casts are a common finding in the patient with renal amyloidosis. Saleeby found them present in over 90 per cent and Dixon in 79 per cent of the instances. Hyalin casts predominate, but granular, epithelial, and waxy casts are also present. Amyloid casts have been mentioned by many authors but there is no evidence which warrants an expenditure of time searching for them. Dickinson⁵⁵ found them rarely, Leube⁵⁶ and Stewart,⁵⁷ never, and Saleeby discovered one questionable instance in a detailed study of the kidneys of 50 cases. White and red blood cells occasionally appear in the urine but their absence or presence is of no particular significance. Bannick and Barker²⁴ reported one case with definite hematuria.

Edema has been found a common occurrence in amyloidosis of the kidneys but its incidence has varied greatly among different observers. Parkes⁴² noted it in 82 per cent of the instances, Dickinson⁵⁸ in 75 per cent, and Bell²⁶ in 50 per cent. On the other hand, Todd⁵⁹ found it only in a small number of instances, Stewart⁶⁰ in 6 per cent and Dixon³⁰ and Rosenblatt¹⁸ in 24 and 34 per cents, respectively. This marked discrepancy is undoubtedly due to the fact that there have been included many instances in which the edema, although coexistent with the renal disease, had been caused by some other condition. The presence of edema in patients with minimal as well as maximal deposits of amyloid in the kidneys led Bell to conclude that there was no causal relationship between the two conditions, but recent studies on nephrosis have suggested a very definite connection. As the amyloid process progresses in the kidneys there is associated a definite increase in the quantity of albumin in the urine. At the Montefiore Hospital many cases were followed in which the clinical extent of the amyloidosis, as measured by retention of the Congo Red, increased simultaneously with the amount of albuminuria. On necropsy the widespread replacement of glomerular tissue by amyloid gave evidence that the kidneys had shared in the progressive increase of amyloid degeneration. The urinary protein is derived from the blood serum protein and as a result of the increasing proteinuria there occurs a progressive depletion of the total serum protein, particularly serum albumin. Because of this diminution in the serum protein there results a marked lowering of the colloid osmotic pressure of the blood.⁶¹ When the serum proteins have been reduced sufficiently the osmotic pressure is no longer able to counteract the hydrostatic pressure in the

capillaries and edema is produced in the same manner that was described by Epstein⁶² for chronic lipoid nephrosis. Examination of the subcutaneous edema fluid found in renal amyloidosis⁶³ discloses that it is poor in protein and similar to that in lipoid nephrosis. The attempts of Shapiro⁵ and others to postulate the existence of an associated lipoid nephrosis in order to explain the nephrotic syndrome in renal amyloidosis have not been convincing. Both clinical and pathological evidence favors the impression that glomerular destruction by amyloid produces the albuminuria and that the clinical features are a consequence of the loss of serum protein. It has been noticed by Floyd,⁶³ Fishberg,⁶⁴ and others that while the blood and urinary findings in amyloid and lipoid nephrosis are very similar with respect to albuminuria, low total serum protein, and inversion of the serum albumin-globulin ratio, the lipemia in the former is much less pronounced. Elevated cholesterol values have been found to occur in about half the instances and doubly refractile bodies are found in the urine only rarely. The cachectic state of the amyloid patient has been suggested as an explanation for the failure of lipemia to occur consistently.⁶⁴ The edema produced by renal amyloidosis is usually moderate and is confined, chiefly, to the lower extremities. Ascites is infrequent.

The absence of hypertension is one of the most distinguishing characteristics of renal amyloidosis. Even when the degenerative process has been so extensive as to cause nitrogen retention, elevation of the blood pressure is rarely seen.^{22, 65} Whether this is due to the debilitated condition of the patient or to some special features of the amyloid, itself, is not known. Of 79 instances of renal amyloidosis in Rosenblatt's series¹⁸ there was found no blood pressure which exceeded 140 mm systolic and only four which exceeded 130 mm. There have been reported, however, a few isolated cases in which uremia due to amyloidosis was accompanied by hypertension. Cardiac hypertrophy and retinal changes have likewise been encountered on rare occasions. Dickinson⁶⁶ observed a case with retinal hemorrhage and cardiac hypertrophy and mentioned a similar one seen by Allbutt. Fishberg and Oppenheimer⁶⁷ described a case with hypertensive neuroretinitis. Noble and Major⁶⁸ also reported an instance of this kind and there are several more occurrences mentioned in the literature. The percentage of uncomplicated cases of renal amyloidosis which terminate in uremia is small but it is to be emphasized that the condition is not a rarity. Dickinson⁶⁹ found it in 10 out of 95 cases (10.4 per cent) and Dixon³⁰ in seven out of 100 (7 per cent). At the Montefiore Hospital in a series of 87 cases, eight (9.2 per cent) were found to have died of renal insufficiency. According to Bartels⁷⁰ and Parkes⁴² early pathologists, including Rokitsky, regarded the amyloid kidney as a form of Bright's disease and even up to recently the uremic manifestations were attributed to a coexisting nephritis. However, the above figures as well as case reports by Zadek,⁷¹ Linder,⁷² and others clearly demonstrate that amyloidosis of the kidneys can produce renal insufficiency without a concomitant chronic nephritis or vascular disease. Fur-

thermore, it is not necessary that the renal disease progress until contraction occurs. The amyloid contracted kidney is an uncommon occurrence. In the eight cases with uremia at Montefiore it was found but once, and in Dixon's seven cases it never occurred.

It is to be seen, therefore, that although amyloidosis is a generalized disease consistently and extensively affecting the most important organs of the body, the course of the illness is essentially that of the underlying disease. There is no definite evidence that either amyloidosis of the spleen or of the liver was ever directly responsible for the death of a patient and there are only a few isolated reports that adrenal insufficiency was ever caused by amyloid involvement. The kidney, which presents the most striking clinical manifestation of amyloidosis, produces a fatal termination in but a small percentage of instances. The combined statistics of Dickinson, Dixon, and our own (305 cases) give the average incidence of uremia as 9 per cent and, as only about 75 per cent of the amyloid cases have renal involvement, the average incidence of terminal uremia in generalized amyloidosis is less than 7 per cent. In view of these findings one may make the general conclusion that in over 90 per cent of the instances amyloidosis, *per se*, is not the cause of death. When the nephrotic syndrome occurs in a case of renal amyloidosis it is indicative of extensive degeneration but many cases have been observed to continue in this condition for many years depending on the course of the etiologic disease. Christian²⁵ reported a case of idiopathic amyloidosis in which extensive edema and albuminuria were present for over three years, and Linder⁷² described a case of amyloid nephrosis secondary to chronic mastoid disease which had lasted for nine years. Stewart⁷³ and Wagner⁷⁴ reported instances of renal amyloidosis which had persisted for 10 and 15 years, respectively.

Both Bartels⁷⁵ and Dickinson⁷⁶ stressed diarrhea as an important symptom of amyloidosis and the latter stated that it was the cause of death in 8 per cent of the cases. He was puzzled, however, by the marked discrepancy between the small amount of amyloid found in the gastrointestinal tract on necropsy and the pronounced clinical symptoms. Observations among the amyloid cases at the Montefiore Hospital reveal the frequent occurrence of diarrhea. But, as the majority of the patients have tuberculosis, we have been inclined to consider the diarrhea as a symptom of the basic disease. There is statistical corroboration of this view in that 65 per cent of the tuberculosis patients have enteric tuberculosis⁷⁷ and only 6 per cent have enteric amyloidosis²¹. Inasmuch as so many of Dickinson's patients were also tuberculous, it is possible that the same situation existed.

When amyloidosis develops in the course of an illness it is indicative of a poor prognosis only because it reflects an unfavorable condition of the underlying disease. As has been indicated amyloidosis, in itself, modifies the clinical course in a very limited number of instances. Both animal experimentation and clinical observations have demonstrated that amyloidosis can undergo spontaneous resolution when the etiologic factor has been removed.

Kuczinski⁷⁸ showed this in studies with mice and clinical reports of cures were made by Fagge,⁷⁹ Gairdner,⁸⁰ Herringham,⁸¹ Walker,²⁹ and Waldenstrom¹⁷ The reason that spontaneous resolution is not more commonly observed is that the etiologic disease is usually one which progresses to a fatal termination In those instances in which the cause of the amyloidosis is a disease amenable to therapy, such as a local suppurative process, resolution will follow upon the healing of the primary disease

Many unsuccessful attempts have been made to introduce specific therapy for amyloid degeneration Potassium iodide, liquor potassium, and various other alkalis were the favorite drugs of the earlier writers Iodide therapy was probably beneficial in those instances in which the amyloid had been due to lues Whitbeck²⁸ recently introduced the use of concentrated liver and reported excellent results in five out of seven patients with osseous tuberculosis It is interesting to note, however, that in the five cases in which the amyloidosis had improved, there also had occurred an associated improvement of the primary bone disease and that in the two fatal cases death had not been due to amyloid involvement The parallel relationship between the course of the amyloid disease and that of the etiologic disease makes it rather difficult to attribute any specific therapeutic action to the liver feedings with respect to amyloid absorption

SUMMARY

The widespread use of the Congo Red test has transplanted amyloidosis from the realm of pathology to that of clinical medicine Unfortunately, this diagnostic aid has come to us at a time when amyloid disease is an unusual occurrence With the exception of tuberculosis, in which it has always been a prominent complication, amyloidosis at the present time is encountered in the average general hospital only on rare occasions Recent studies have revealed that amyloidosis may be associated with almost any type of disease, with or without suppuration, and that in many instances no etiologic agent is discovered even after postmortem examination As the major underlying disease, tuberculosis, is one of young adults, it naturally follows that amyloidosis is found mainly in this age group and, omitting exceptional instances, it takes from one to two years for the degeneration to manifest itself The ability to make a clinical diagnosis depends on an appreciation of the physiological and pathological changes produced by the degenerative process on the organs most frequently involved Constitutional characteristics such as anemia, cachexia, and waxy pallor are too intimately related with the underlying disease to be of diagnostic import When degeneration of the liver and spleen is sufficiently extensive these organs may be felt as hard, smooth, non-tender masses Involvement of the adrenals is a frequent occurrence and, although many amyloidosis patients exhibit features of adrenal insufficiency, true Addison's disease has been found on exceedingly rare occasions It is degeneration of the kidneys which produces the characteristic manifestations A patient with tuberculosis, or other debilitating disease, who shows progressive albuminuria,

depletion of serum protein, inversion of the serum albumin-globulin ratio, edema, no hypertension, and other associated findings of the nephrotic syndrome warrants a tentative diagnosis of amyloid nephrosis. The Congo Red test furnishes the confirmation. The number of proved cases of amyloid nephrosis overwhelmingly exceeds that of chronic lipid nephrosis and many instances have been recorded in which the latter diagnosis had to be changed to that of renal amyloidosis after postmortem examinations. It appears, therefore, that even in the absence of the diseases usually associated with amyloidosis any occurrence of the nephrotic symptom-complex requires the performance of the Congo Red test. There is a marked disproportion between the extent of amyloid degeneration and its effect on the clinical course of the patient. Despite the most widespread affection of the liver, spleen, and adrenals, in the great majority of instances, the ultimate prognosis will be entirely independent of the amyloid disease and depend only on the course of the underlying condition. In a small percentage of the cases renal amyloidosis terminates in uremia but extensive degeneration may be present for many years without any clinical manifestations of renal impairment. Many attempts have been made to introduce specific therapy for amyloidosis but their success has been found directly proportional to the behavior of the basic disease. Experimental and clinical observations have revealed that when the causative agent is removed the degeneration regresses spontaneously. However, as most of the cases are caused by diseases which terminate fatally, amyloid regression is an unusual occurrence.

NON-PAINFUL FEATURES OF CORONARY OCCLUSION *

By S. MARX WHITE, M D , F A C P , *Minneapolis, Minnesota*

THE symptoms signalling the onset of occlusion of a coronary artery with infarction, when thrombosis furnishes the determining factor in completing the closure, are striking and dramatic. In times past, certain reasons no doubt contributed to the failure of clinical recognition of the nature of the pathologic process causing the symptoms. Prominent among these reasons is a certain similarity in the character of the pain to that in the angina pectoris of effort and the fact that coronary occlusion often develops in patients with that symptom-complex, or less often may furnish a basis on which later anginal symptoms develop. The mere fact that the pain with thrombosis is more prolonged, does not cease with cessation of effort, and is accompanied and followed by signs of persisting damage in the myocardium, did not become recognized until recent years and is still too often disregarded by the family physician and surgeon. The early, frequent, routine study of the leukocyte response in the blood, and of the body temperature under conditions not clearly inflammatory or infective has been useful in establishing the presence of infarction, while the growing availability of electrocardiographic data has made the diagnosis common.

In the famous thesis by Rene Marie¹ in 1896 there is a clear statement of the pathologic relationship or sequence of coronary sclerosis, coronary thrombosis and infarction of the heart wall with resulting rupture of the heart, fibrous plaques in the myocardium, cardiac aneurysm and intraventricular thrombosis.

It is interesting in this connection to note the clarity with which Marie brings out the distinction in the histories of the cases between the angina of effort which he ascribes to a purely functional ischemia, and those other anginal paroxysms in which the ischemia becomes organic, due to a definite arterial obliteration and announced by a paroxysm in general more violent and more prolonged. The symptoms accompanying this *angor pectoris* and *mal angineux* are brought out with interesting detail and accuracy. Cases of infarction without pain are recognized. It is shown that survival is common, with development of fibrous plaques and of parietal aneurysm. He writes "Diagnosis is easy enough," and adds that it is not in the power of any therapy or medicament to restore life and function to this ischemic and necrotic part of the organ.

Although Dock² in 1896 reported a case of coronary thrombosis, recognized during life and proved at autopsy, and Huchard³ in 1899, and Krehl⁴ in 1901, discussed coronary thrombosis from the clinical standpoint, it re-

* Read at the Chicago meeting of the American College of Physicians, April 19, 1934

maintained for Obratzow and Straschesko⁵ in 1910 to call attention to the feasibility of clinical diagnosis, and for James B Herrick⁶⁻⁹ in 1912 and again in 1918 and 1919 to describe sudden obstruction of the coronary arteries and to establish the modern differentiation of the symptomatology from that of the angina of effort Libman¹⁰ and Levine and Tranter¹¹ contributed to the subject within the above period of Herrick's writings. Immediately following that the literature in this country began to grow, bringing into relief the clinical features as seen by many men, until Christian¹² in 1925 called cardiac infarction "an easily diagnosable condition." Levine's¹³ monograph of 1929 has become a vade-mecum for students of the heart.

Aside from the characteristic pain with its duration greater than that in angina pectoris, certain features have become recognized as indicative of acute muscle damage, i.e. of the infarction caused by the abrupt continued interference with an adequate or near-adequate blood supply to the affected portions of the myocardium.

Occlusion of the smaller coronary branches has received much consideration as a cause on the one hand of precordial pain, and on the other hand of the small scars so often found at autopsy associated with atheromatous coronary vessels. While the pain alone may be indicative of deprivation of blood supply to an area at that time, it is not sufficient for the final diagnosis of infarction. If the damaged area is too small to cause such responses as leukocytosis, pericarditis, mural thrombosis, characteristic lowering of blood pressure or abrupt and progressive changes in the electrocardiogram, it is more than probable that the heart wall will heal without yielding at that particular site to intra-cardiac pressure. Qualification is necessary in that, as pointed out by Wearn,¹⁴ the classical signs may not appear when infarction occurs in the presence of heart failure. However, the adequate treatment of the failure in such a case requires protracted rest periods, and the serious error of a too short control is not likely to occur. The small scars, usually multiple, disseminated, and sometimes very numerous, still await actual demonstration by pathologists of the relation of each scar to an area of occlusion in the vessel. Scarring may be inferred clinically when persisting damage to conduction paths is demonstrated by electrocardiographic methods, but to diagnose the process in the presence only of myocardial inadequacy is still precarious. This is particularly true in hyperpiesia where in late stages severe dilatation and decompensation, with marked alteration of the complexes in the electrocardiogram, often occur without scars being found at autopsy. The intimate relation between coronary sclerosis and the smaller areas of myocardial fibrosis makes the former a widely accepted cause of the latter, but controversy will continue until more conclusive evidence clinically and pathologically is at hand.

Embolism of coronary vessels, first described by Virchow¹⁵ has been recently reviewed by Saphir.¹⁶ Its rarity, immediate fatality, and possibility of clinical diagnosis only by inference if survival should occur make consideration here unnecessary.

When gross infarction results from sudden closure as with thrombosis in a coronary vessel, the initial disturbances such as the pain with or without shock-like phenomena in the circulation, are so striking as to divert attention from the other features. Unless, however, careful attention is paid to these, which may be called the non-painful features of coronary occlusion, the opportunity to recognize actual infarction may be missed. Furthermore, the whole picture of sudden coronary occlusion may be so closely copied by certain other conditions that only painstaking study can differentiate them.

An appraisal of not only the painful, but the non-painful features is necessary if accurate diagnosis is to be made, and if we are to take further steps in determining during life whether actual necrosis of a considerable or important part of the heart wall has occurred.

Fever and leukocytosis are two signs of infarction which present whenever this process occurs in any considerable amount anywhere in the body and are the two features aside from the pain most certain to occur with the infarction of coronary thrombosis.

Fever is occasionally lacking and seldom exceeds 102° F by rectum. It is usually nearer 101 to 101.5° , is irregular in its development from day to day, begins early as a rule, varying from three to four hours to two days after the onset, and may last for from one to two weeks, though it is usually or often of shorter duration. Because of the shock-like character of the onset in many cases, mouth temperatures do not reveal the fever and Levine's insistence on rectal temperature readings as a routine is well taken.

Leukocytosis likewise is rarely absent, but is seldom or never extreme, figures of 10,000 to 16,500 being the more common and 22,600 the upper limit I have observed. A leukocytosis of 25,000 or more is reported by Levine (loc cit). P. D. White¹⁷ states that the count may rise to 30,000. Leukocytosis may be found very early, it was seen in two of our cases as early as two and three hours after the onset of pain, and has been reported by Libman and Sacks¹⁸ in one case as occurring one and one-quarter hours after the onset. The count may be elevated for from three or four days to one and even two weeks. What may be the factors preventing leukocytosis in the occasional though rare case, remain unknown. I have not found it entirely absent throughout the early days in any case of acute infarction coming to autopsy in which an adequate clinical study with repeated counts had been made. I have gained the distinct impression, formed through long observation of recovered cases as well as of autopsies in fatal cases, that the most important factor in temperature elevation and especially in the height of the leukocyte count, is the size and surface extent of the infarcted area. That this factor is determined as much or more by the character of collateral and possible Thebesian circulation in each individual as by the site of occlusion has become apparent.

The blood pressure is nearly always lowered as compared to previous levels in the individual. If it is found only slightly above normal or if it is within the normal range, and if records of previous pressures are inadequate

or unavailable, the fact that there is a drop may not be recognized at first. Periodic elevations, or elevations later during convalescence may be suggestive of previous arterial hypertension, or there may be an enlarged forcible apex beat displaced to the left, together with the percussion outline and roentgen-ray silhouette typical of the left ventricular hypertrophy which accompanies it. In several instances I have seen the blood pressure remain down near the newly acquired levels, when hypertension previous to the occlusion had been known to exist, but with recovery usually the pressure returns, to or toward the former basal levels.

The drop in blood pressure may be extreme, or it may not at first be marked, but lowering may develop in 10 or 12 hours to two days or even later, and may reach its lowest levels from two to four days after the onset of symptoms. I have watched a case in which the readings became lowest on the third day and although variable remained near 70 systolic and 60 diastolic for four days, gradually to rise later to near normal. A drop as marked as this is not common, but figures near 90 systolic and 75 to 80 diastolic pressure are frequently noted in our records. In cases furnishing evidence of previous hypertension these low levels are seldom reached, but the low pulse pressure is often noted.

The pericarditis which develops following coronary infarction is seldom accompanied by demonstrable effusion. A patch of epicardial roughening with fibrinous deposit will cover the region where an infarct reaches the surface. The clinician will find a friction rub in proportion to the frequency with which he listens during the first two to three weeks, for the rub may be very evanescent. In two cases I heard the characteristic and unmistakable sounds only once in repeated observations. When heard more persistently, which is the rule, they may appear and disappear over a period of a week or more. Accumulated experience shows that the rub is heard in only one of seven or eight cases. Levine notes it as heard in 13.8 per cent of his series. When pericarditis develops over any area except the anterior surface of the heart it is of course, inaccessible to auscultation. The fibrinous exudate is aseptic and does not spread beyond the area in which tissue damage reaches the epicardium. The amount of fluid free in the pericardial sac, though often increased is not enough for clinical recognition. That the absence of demonstrable effusion may be important in diagnosis is illustrated by the case of a man 46 years of age, free from arthritic symptoms, with sudden precordial pain, fever to 101.8° F, leukocytosis to 14,500 and with progressive changes in the electrocardiographic tracing from time to time. These features, including the age, led to the impression at first of coronary infarction. This was strengthened for a brief time when a pericardial friction rub was heard, but the spread of the rub over the entire ventral surface of the heart and the development of a large pericardial effusion caused a revision of this opinion and the final diagnosis of rheumatic carditis was confirmed by autopsy at a much later time.

Intracardiac thrombosis occurs when the infarction reaches the endocardium. The occurrence is signalled in life only by embolic phenomena. The expression of these is not always clear and unequivocal. An area of infarction anywhere in the body, if the area is large enough, will cause fever and leukocytosis as a rule. The signs of lodgement in brain, spleen, kidneys, lungs and other viscera are generally recognized. Routine and persistent search for these signs often gives crucial evidence which would otherwise be missed. The signs of embolism in so-called silent areas of the brain are difficult to interpret. A habit of recording on first examination the character and location of each individual peripheral pulse has enabled me to recognize the embolic character of phenomena in legs and forearms which would otherwise be less definitely recognizable. The radial and ulnar, posterior tibial and dorsalis pedis arteries are known to be frequently anomalous in their course, with resulting absence of pulsation at the usual sites. They are likewise frequently the site of embolism. The disappearance of a pulse in a single vessel known to be previously pulsating, when accompanied by corresponding circulatory changes in the area, is the most convincing clinical evidence of occlusion we possess. The pain, swelling and degree of color change of the part may be minimal and insufficient in themselves for the diagnosis of embolism. If, however, the observer has proof that the absence of a pulse is due not to the anomalous course of a vessel, but to disappearance of the pulse, then the diagnosis of a pathological closure rests on solid ground.

The electrocardiographic changes expressive of muscle damage are the subject of an extensive literature. Changes seen in the electrocardiogram vary from striking and distinctive, characteristic on occasion of the artery involved, i.e. whether right or left coronary, to changes which are minor and indeterminate. For this reason tracings should be taken at the earliest time possible, and should be repeated every two to four days at first, and at longer and suitable intervals later in the course. A routine health examination which includes an electrocardiogram furnishes an excellent basis for comparison. I have been fortunate in a number of cases in having on hand tracings taken before the infarction. The most definite type of electrocardiographic evidence is that derived when frequent, successive tracings show conclusive differences, for then we have evidence not only of muscle damage but of progressive change.

There is promise that the number of cases, now estimated at 15 to 20 per cent, in which no change is found when using the conventional arm and leg leads, will be greatly reduced by the use of antero-posterior chest leads, a method especially studied by Wood and his associates^{19, 20}

Certain familiar features of the clinical examination may or may not appear, and may give weight to the diagnostic conclusions. They are the shock-like condition and appearance of the patient in the early stages of the infarction, persisting for days in some, altered and often dull or distant heart tones, a gallop rhythm, signs of congestive failure, including changes

noted in the urine, dyspnea, Cheyne-Stokes respiration and the modifications of it often called paroxysmal dyspnea, acute emphysema of the lungs, and finally but of extraordinary interest and importance, changes in rate and rhythm of the heart

Precordial pain alone is not adequate for the diagnosis of cardiac infarction. There is a group of cases, considerable in number, with pain of the same character as that occurring with infarction, in whom none of the other major signs develop. Without fever or leukocytosis, the blood pressure changes, pericarditis or embolic sequelae, and with no successive changes in the form of the electrocardiogram we may suspect sudden closure of a small branch or twig. If this has in fact occurred in such a case the danger of the sequences of gross thrombosis is minimal or absent and prolonged periods of rest are not needed. In fact, the management is essentially that of the other underlying arterial and myocardial conditions inferred or actually diagnosed. Conditions other than infarction can, however, occur and be indistinguishable by the pain alone. P. N., a strong healthy man of 54 years, was eating an ice at the end of lunch when seized with severe retrosternal and constricting type of pain. He was seen within a few minutes by an accomplished and experienced physician who had no doubt about a diagnosis of coronary occlusion. When seen by me at the end of a half hour my opinion was as definite as that of my colleague, that the pain and shock-like condition were typical. With morphine hypodermically in repeated doses up to a total of one-half grain, the pain subsided to disappearance in about 50 minutes from the onset, and within four hours he was feeling well and remained so. In the succeeding days the temperature did not go above 99° F, the highest leukocyte count, taken once and twice each day, was 8,900, the percentage of polymorphonuclear neutrophils always below 65. The limits of blood pressure readings were 150/82 and 120/90. Repeated electrocardiograms showed no deviations from normal complexes, and were identical on all occasions. Studies of the esophagus for lesion were negative, but a cholecystographic dye study gave typical shadows of a partially functioning gall-bladder filled with calculi of about 7 mm diameter and less. Final pathological proof is lacking as yet, but there is no reasonable doubt as to the calculus cause of this man's symptoms. This is not an isolated instance, the citation being given to illustrate the need for serious study of the non-painful features promptly and continuously following the initial events. The combination of gall-bladder disease with true anginal symptoms and with sudden coronary occlusion is not rare, and requires observations with the accumulation of much evidence for appraisal of the true values. Erroneous impressions again were given by the pain in the case of A. E., male, aged 63, seen with Dr. Norman Johnson, in which autopsy showed a ruptured aorta with extensive interstitial hematoma dissected to the base of the heart around the coronary orifices, as well as distally to the bifurcation into the common iliac arteries. Death occurred four days after onset of symptoms. Fever to 100.6° F, leukocytosis to 16,600, signs of

obstruction in right brachial and right cerebral artery were recorded. Electrocardiographic tracings taken 48 hours apart showed minor deviations from normal with inversion of T_1 in the first, and marked changes from this tracing in the second. This was satisfactory evidence of rapid changes in the myocardium. Although it had been discussed, a diagnosis of rupture of the aorta was dismissed. The error lay in failure to take a roentgen-ray film of the chest to determine, if possible, widened mediastinal shadows. The interest lies in the fact that certain of the most crucial signs such as those of arterial closure, simulating embolism and rapidly changing electrocardiographic complexes mimicking the changes seen in myocardial infarction can develop.

The cases of infarction of the heart simulating acute abdominal conditions, first brought to attention by Levine and Tranter,²¹ have become so well known that they are now feared and sometimes avoided by even the type of surgeon who makes a diagnosis by history and abdominal palpation alone. The cases with pain minimal or absent require dependence on the non-painful features for diagnosis and the value of their study is correspondingly increased.

In proportion as evidences of the phenomena associated with the initial events of infarction are multiplied, the certainty of recognition of coronary thrombosis grows. The evidence obtained may not allow a diagnosis but may leave the clinician with diagnostic impressions only. This status should be avoided if possible. No opportunity to collect evidence should be overlooked during the early stages when the evidence is obtainable.

The responsibility of the physician is very great, both to insist on adequate rest after infarction, and to avoid unnecessary time and expense on the part of the patient if no infarction has occurred.

The question as to the period of bed rest required by a patient with an infarcted heart wall receives little discussion in our literature. Rupture through the freshly infarcted area occurs most often early, i.e. in about the second week, less often as late as the third. Patients are usually in bed at least over this time but after this period practice varies widely. Experience over many years has led the writer to require longer bed rest than formerly. It is believed now that at least eight weeks are necessary if we are to minimize the likelihood of such crippling sequelae as aneurysm of the heart wall with its attendant rupture, intra-aneurysmal thrombosis and general interference with good function of the remaining muscle. This requirement is a minimum and is increased if there is recurring pain, signs indicating extension of the infarcted area, persistent low blood pressure or other features suggesting delay in the firm fibrous replacement desired. When time sufficient to secure this has been given, many patients regain a gratifying degree of capacity. Not many cases with the 17 and 20 years' survival, as reported by P. D. White,²² are recognized, but recovery and years of relative usefulness are now known to be common, and can be definitely increased by prolonged and adequate rest with freedom from

strain immediately following the infarction. The basis on which this recovery rests can be only by adjustments in collateral circulation, an idea first given its true emphasis by Heirick (*loc cit*) and now expressed throughout the literature. Immediate adjustment of collateral circulation must occur if life is to continue and repair is to progress. Examination of many hearts of patients who have survived for varying periods after occlusion shows more or less increase in this collateral circulation with hypertrophy, as well as dilatation of the vessels involved. This process takes time—how much we do not yet know. The error of the physician should be on the side of safety. It is in this connection that the immediate and persistent study of the non-painful features has its greatest value. If one can be satisfied that a gross infarct does not exist the period of rest can be greatly shortened, and the three and four weeks' period in more common use suffices. It is just as necessary to avoid impressing the patient too severely with a sense of his limitations in this situation as it is to demand adequate time for healing in a case with gross infarction. Whether further degenerative change in the coronary vessels with subsequent occlusions can be prevented, and if so, how, is a matter for future determination.

Disturbances of rate and rhythm of the heart occur in association with the changes in the heart wall due to arterial occlusions. They are the subject of an extensive literature. The writer's records cover auricular premature beats, fibrillation and flutter, nodal premature beats and tachycardia, ventricular premature beats and tachycardia, bundle branch block and partial and complete block, including delay in auriculo-ventricular conduction.

Some of these, such as the tachycardias, may require prompt and specific treatment as life-saving measures in order to relieve the heart muscle of the added strain imposed. Premature beats are common without knowledge of coronary occlusion, and require treatment only when frequent or a source of anxiety to the patient. Extrasystoles and the tachycardias are to be treated by commonly accepted methods, with one exception. This refers to ventricular tachycardia. In this condition the use of digitalis should be avoided. Levine (*loc cit*) cautions against it. Davis²³ shows its disadvantages and dangers. Nathanson²⁴ in his remarkable studies on the human heart, showed that digitalis definitely prolonged the period of cardiac standstill induced by pressure on the carotid sinus. Its effect is probably the same under the circumstances considered here. Quinidine appears to be a safer drug in this particular condition. I have repeatedly seen it apparently control the tachycardia and restore normal rhythm. In one instance death occurred four days after cessation of the ventricular tachycardia and discontinuance of the drug, undoubtedly from other causes related to the infarction. H. D. Levine,²⁵ in an experimental study of cats, found that quinidine definitely inhibited the facility with which ventricular fibrillation could be produced by faradic stimulation, and suggested that the results offered a rational background for proper quinidine therapy as a method for preventing sudden death in those conditions in which ventricular fibrillation

is prone to occur. Ventricular tachycardia is generally recognized as such a condition. Quinidine is a definite poison to, as well as remedy for, the heart, and is believed to be capable in overdosage, of causing ventricular fibrillation. Hence the exquisite care needed if it is to be used properly.

The importance of conduction defects as evidenced by the electrocardiogram lies in two directions. First is the aid given in localizing the damage to the heart wall. Indirect reference to this was made by Herrick²⁶ in 1925 when he called attention in a parenthesis to the fact that "some parts of the heart are less vital, more indifferent, than others." Defects in auriculo-ventricular conduction show involvement of the septum near the junction of auricles and ventricles, while bundle branch block evidences an involvement lower in the septum after anatomical division of the conducting bundle has occurred.

The second and greater importance of conduction defects lies in the high immediate mortality when complete auriculo-ventricular dissociation occurs. Hansen²⁷ has published electrocardiograms from a case seen also by me in which complete heart block developed on the fifth day and disappeared on the ninth, although the patient died suddenly on the twelfth day. In my records of five cases of complete block accompanying myocardial infarction, four were fatal.

In this condition also prompt and proper treatment may be a life-saving measure. In the case of W H P, aged 60, the pulse stopped beating and the heart tones disappeared 12 hours after the initial pain. Within one minute a four inch sterile needle was thrust through the fourth right inter-space 1 cm to the right of the sternum and directed to the assumed position of the right auricle, 0.5 c.c. of adrenalin was injected through it. Within three seconds a radial pulse was noted, first as a single isolated beat, and after two or three seconds more the pulse assumed its usual character. Five and one-half hours later respirations ceased and pulse beat and heart tones again disappeared. The adrenalin injection with the same technic was repeated. On this occasion when the needle reached the depth it was apparent by its rhythmic motion that the heart was beating although no tones could be heard. No response to treatment occurred. Autopsy showed extensive atheromatous changes and a thrombus beginning about 2 cm. from the sinus of Valsalva, in the left coronary artery. There was a single needle puncture found entering the right auricle in its lower part. No hemorrhage from it was apparent. The effects of adrenalin have long been known. The excellent studies by Nathanson^{24, 28} show that epinephrine in its natural laevo-rotary form had a powerful effect on the impulse-initiating mechanism of the ventricles in man, and consistently prevented cardiac standstill by the induction of an idio-ventricular rhythm.

In concluding it may be said that when occlusion of a coronary artery occurs the mode of onset of symptoms may be strongly suggestive of the pathologic changes, but that diagnosis should not be considered easy. Given a patient seized with precordial pain apparently typical in character, if there

is survival of the initial events, which is probably the rule rather than the exception, immediate and continuing study of the non-painful features of the case is requisite for accurate appraisal. If, in fact, there is an area of infarction large enough to give fever, leukocytosis, pericarditis, intracardiac thrombosis or considerable changes in the ventricular complexes of the electrocardiogram, a long period of rest is advisable in order to promote firm, unyielding scarring of the area. A minimum of eight weeks is advised, this period to be extended if repair seems halted or inadequate. If the signs of infarction are lacking, less drastic restrictions are in order, and the diagnosis may be in question. Pain alone, regardless of how typical its character seems to be, is inadequate for an accurate and final diagnosis. Rheumatic carditis, pulmonary embolism, gall-bladder disease, and other lesions of the upper portion of the abdomen, and rupture of the aorta with interstitial hematoma present particular difficulties in differentiation.

Coronary occlusion may occur without pain and cause gross infarction. Study of the non-painful features gives our only clues to the diagnosis. Two of the many changes in rate and rhythm, i.e. ventricular tachycardia and heart block are of particular importance in prognosis and treatment.

PERSONALITY STUDY IN THE PRACTICE OF INTERNAL MEDICINE *

By EDWARD WEISS, M D , F A C P , *Philadelphia, Pennsylvania*

IN the course of a recent study of psychiatric education in 60 medical schools in the United States, Ebaugh ¹ questioned the professors of medicine as to the frequency of psychiatric problems in general medicine and found their answers to strike an average of 35 per cent Ziegler ² questioned 80 physicians in general practice in New York State as to the percentage of patients consulting them who had no very definite bodily disease as a basis for their complaints and found their answers to average about 20 per cent From these and other sources † there is good evidence that a large number of illnesses encountered in general medicine are of psychic origin Recently I have studied 200 consecutive private patients, classifying them as follows

(1) Those in whom the illness seemed to depend entirely on emotional problems,

(2) Those in whom the illness seemed in part dependent on emotional problems,

(3) Those in whom an emotional problem did not seem to enter into the cause of the illness Thirty-five per cent were placed in the first group, 35 in the second and 30 in the last Space does not permit the citation of many examples to illustrate the basis of this classification But, as an example of the first group there is the patient who undergoes repeated abdominal operations in a vain effort to get rid of pain or discomfort Everybody engaged in hospital practice has seen many such individuals The following case is a fairly typical one

A young woman at the age of 19 had her first attack of pain in the right lower quadrant At 20 the appendix was removed Six months later she had a pelvic operation because of painful menstruation At 26 she had her third operation for abdominal adhesions For the next four years she complained more or less constantly and had been in bed for considerable periods because of the pain in the right side Stricture of the right ureter was suspected but not proved and, finally, after a great deal of hospital investigation a fourth operation was performed in the belief that there was disease of the large bowel, but all organs were found normal

Here, then, was a patient who had been practically incapacitated for many years and who, during this period of time, had been repeatedly subjected to searching physical investigations and many abdominal operations What

From the Department of Medicine, Temple University School of Medicine, Philadelphia, Pennsylvania

† Moersch,³ in an analysis of 500 consecutive patients seen at the Mayo Clinic, reported psychogenic factors of varying degree in 44 per cent, Stevenson,⁴ in a study of 150 patients presenting themselves to a gastrointestinal clinic, states that there was an important emotional problem in two-thirds of the cases, Reynolds,⁵ in a study of 935 unselected private patients encountered in the practice of internal medicine, concluded that 21 per cent were psychoneurotics

the many physicians attending her had not discovered or did not know the significance of was that this long illness began shortly after the fourth of her five sisters married and this patient thought that she would in all likelihood remain a spinster and would then endure a life of drudgery and comparative loneliness. Meek and submissive, unattractive and unintelligent, she unconsciously turned to illness when she found it impossible to compete with her sisters' superiority. Further personality studies disclosed her very immature emotional development and confirmed the opinion that the sister's marriage had precipitated an invalid reaction in this psychoneurotic individual.

How does modern medicine handle this large group of patients? As Forsyth,⁶ in a somewhat similar study of English medicine, has well stated, these patients are searchingly investigated by means of medical history, physical examination and laboratory studies, and then treated (1) as organically diseased, being submitted to unnecessary medical or surgical treatment, as in the example above cited, thus intensifying the neurotic condition, or (2) they are told that the physician does not *think* anything is the matter but with suspicion cast upon some organ or system which needs watching and care, as happens very often with regard to the symptom of fatigue and the suspicion of pulmonary tuberculosis, and (3) lastly in some instances such patients are still told that there is no evidence of organic disease and that the whole thing is "functional," "imaginary," "all in their head," or they are left with the implication that they are liars or malingerers, or referred to as "damn neurotics" with the unfortunate kind of care that must necessarily go with such a characterization. In other words the attitude of modern medicine is not so very different toward these patients from that described in 1884 by Clifford Allbutt,⁷ who said, in speaking of the visceral neuroses: "A neuralgic woman seems thus to be peculiarly unfortunate. However bitter and repeated may be her visceral neuralgias, she is either told she is hysterical or that it is all uterus. In the first place she is comparatively fortunate, for she is only slighted, in the second case she is entangled in the net of the gynecologist, who finds her uterus, like her nose, is a little on one side, or again, like that organ, is running a little, or it is as flabby as her biceps, so that the unhappy viscus is impaled upon a stem, or perched upon a prop, or is painted with carbolic acid every week in the year except during the long vacation when the gynecologist is grouse-shooting, or salmon-catching, or leading the fashion in the Upper Engadine. Her mind thus fastened to a more or less nasty mystery becomes newly apprehensive and physically introspective and the morbid chains are riveted more strongly than ever. Arraign the uterus, and you fix in the woman the arrow of hypochondria, it may be for life."

Why has there been so little progress in the handling of this class of patients? It does not seem to me that the reasons are difficult to find.

The physician of ancient times was concerned with the spiritual basis of illness but the structural concept introduced by Virchow led to the separation

of illness from the psyche of man and a consideration of disease as only a disorder of organs and cells. With this separation of disease into many different ailments came the development of specialists to attend to all of these distinct diseases. With the specialists came the introduction of instruments of precision and the mechanization of medicine began. Medicine now contented itself with the study of the organism as a physiological mechanism, impressed by blood chemistry, electrocardiography, etc., but unimpressed and, indeed, often holding in contempt the psychological background of the individual which was not considered as scientific as the results of laboratory studies. This period may, in truth, be referred to as the machine age in medicine. It is not to be denied that remarkable developments have occurred during this period of laboratory ascendancy but it also must be admitted that the emotional side of illness has been almost entirely neglected.

Even today the preparation in psychological medicine afforded our students is very inadequate in the great majority of medical schools. Ebaugh,¹ in the study already referred to, found that only 13 grade A schools give reasonably complete courses in psychiatry and that there appears to be a lack of psychiatric teaching personnel in approximately 85 per cent of the schools visited by the committee.

As a consequence of this structural and physiologic tradition in medicine a large number of physicians pride themselves upon their unwillingness to concede the absence of physical disease when dealing with an obscure illness. In discussing such a patient they are apt to say "but there must be something the matter" meaning that there must be a physical basis for the illness. And they furthermore believe that future researches along the lines of physical medicine will eventually uncover the hidden causes—infectious, allergic, endocrine or metabolic—responsible for such obscure illnesses.

Still another group of physicians are willing to believe that psychic factors have something to do with illness but they have only a vague notion of the part they play. They recognize that there is a "neurogenic factor" or a "large nervous element" present but they look upon this feature as a secondary one and probably a consequence of the physical disorder.

While freely acknowledging the relation of psychic causes to such physiologic phenomena as blushing, weeping, goose flesh, vomiting, diarrhea, etc., they nevertheless find it difficult to believe that more prolonged (chronic) disturbances of a physiologic nature can possibly be psychic in origin.

They are the physicians who remark about a patient,—“but he doesn't look neurotic,” perhaps imagining that such a patient should by his general apprehension or by evidences of physical nervousness betray the fact that neurosis is present. Their approach to the emotional problem is apt to consist of the question “Are you worried about anything?” Unfortunately most neurotics do not betray their neurosis in their appearance nor is the approach to their emotional problem so simple that the direct question—“Are you worried about anything?”—will produce material of importance.

More specifically then, what are some of the diagnostic and therapeutic

problems of the neuroses and how are they to be approached? One may conveniently choose four closely related headings for the discussion. First, failure to recognize neurosis and treating the patient as organically diseased. This happens most frequently, as already suggested, because modern clinical medicine attempts to establish the diagnosis of "functional" disease by ruling out organic disease through medical history, physical examinations and laboratory investigation. The point that I particularly wish to make is that the diagnosis of "functional" illness must be established not simply by exclusion of organic disease but on its own characteristics as well. In other words neurosis has its own distinctive features to be discovered by personality study. Only in this way can serious errors in diagnosis and treatment be avoided. If the above statement is admitted it must naturally follow that personality study is just as important in the problems of chronic illness as laboratory investigation.

This kind of an approach will do a great deal to relieve the fear of the physician that he is missing something organic because it will supply him with additional information to confirm his diagnosis of functional disease. It is perfectly true, of course, that organic disease can be overlooked and the patient treated as a neurotic, which is the reverse of the situation above mentioned. Physicians are constantly harassed by this fear of overlooking organic disease. They are of the opinion when dealing with this class of patients that the structural disease is hidden and will come to light with the passage of time. Again this may be true but in the majority of instances is not. A recent study from the Mayo Clinic is illuminating in this regard. Macy and Allen⁸ studied the records of 235 patients approximately six years after the diagnosis of chronic nervous exhaustion had been made, with the idea that if the clinical picture at the first examination was due to unrecognized organic disease, such organic disease should be detected by subsequent examinations over a period of years. The accuracy of the diagnosis proved to be about 94 per cent, which seems to indicate that this kind of functional illness, at any rate, is not due to organic disease. It is interesting to note in passing that 289 separate operations had been performed on 200 patients of the group that they studied.

The answer, therefore, to the reverse of the problem is substantially the same, careful physical studies plus personality investigation. In other words, one will not be so apt to overlook organic disease and treat the patient as a neurotic if personality study fails to reveal the background for neurosis. One may say further that it is unsafe to make a diagnosis of neurosis in an adult without evidence of a previous neurotic difficulty. The adult does not suddenly become neurotic unless he has had the background for a neurosis within him which personality investigation would reveal. I regret the necessity for continuing to stress personality investigation and saying nothing of the technic for so doing. But it is impossible to consider this large subject in any adequate manner at this time. Generally stated one may find important clues in a study of problems centering around vocational, religious,

marital and especially parent-child relationships. One point of special importance deserves consideration here and that is the relation of sexuality to neurosis. Ever since the introduction of the epoch-making studies of Freud in the application of psychoanalysis to the problems of neurosis, medicine has misunderstood his conception of sexuality. First, sexuality has been considered from the narrow view point of genitality, of course it is much more than that. And secondly it has mistakenly been believed that Freud considered these disturbances in genital activity to be the sole cause of the neuroses. This, indeed, is far from the truth. While the problem of sexuality in medicine is a very large one it may be stated for general purposes that difficulties in the sexual sphere serve as a revealing index to a neurotic personality and are to be looked upon only in that light. In other words, in much the same way that urea retention serves as an index to an approaching uremia so do disturbances in the sexual life of the individual, such as varying degrees of frigidity in the female and varying degrees of impotence in the male, serve as a reliable index to the kind of a personality that is very liable to the development of a neurosis.

The second problem of importance in the diagnosis of the neuroses has to do with the proposition of the recognition of a "nervous element" but ascribing it to a structural alteration which may have nothing to do with the psychic problem. This happens very often in women with anxiety or hypochondriacal symptoms in whom benign enlargements of the thyroid gland may be discovered. It happens frequently in regard to headache and supposed sinus disease and in many other instances too numerous to mention. The physician must always ask himself—are the organic defects revealed by physical examination sufficient to explain all of the symptoms? And the second question which naturally follows this one—what may be the meaning of the symptom from the standpoint of behavior? In this connection one can speak of the necessity for personality study in many patients who are to be operated upon. A slight operation in a patient not recognized as potentially neurotic will sometimes lead to a more severe illness and an extreme degree of invalidism.

Thus, a young woman was subjected to a lumbar puncture in the course of a complete examination to find the cause of frequent headaches. Immediately she became ill with more severe headaches, pain in the back and various bowel disturbances and remained bed-ridden for nine months. This was her infantile way of expressing her disapproval of her brother's marriage,—her only brother to whom she was closely attached and who acted in the capacity of father to the family. The slight operation acted as precipitating agent for the neurosis and inadequate psychologic understanding on the part of the physician permitted the illness to continue. She recovered when the meaning of the illness was made clear to her and shortly afterwards she married an older man.

The third problem to be discussed is more difficult and that is, when there is evidence both of organic disease and psychological factors the evaluation of the part played by each in producing the illness.

A young white man first seen in April 1933 complained of severe epigastric discomfort. The illness began one year before but there had been slight symptoms of gastric distress on occasions since puberty. Roentgen-ray studies showed a small part of the stomach herniated through the esophageal hiatus and it was believed that this anomaly explained his illness.

But it also developed that coincident with the onset of the present illness he had had an affair with a girl and (associated with circumstances that I will not take the time to discuss) he developed premature ejaculation and feared impotence. He thought of little else, repeatedly tried sexual intercourse with various kinds of women in order to prove himself potent, became depressed, had a dejected appearance and complained of stomach symptoms. So deep was his mental depression that even the anticipation of graduating from professional school, for which he had made tremendous sacrifices and to which he had always looked forward as his great objective, occasioned him no pleasure. He even considered forsaking his profession.

I advised him to discontinue attempts at intercourse until he had graduated, then we would discuss what treatment he must undergo. His stomach symptoms disappeared and his mental outlook improved somewhat in the succeeding months.

I felt that it was very difficult to evaluate the part played by somatic and psychic factors in this case but it is obvious that both are highly important in understanding the illness. Here, as previously discussed, the disturbance in his sexual activity served only as an index to a very passive and dependent kind of personality prone to develop neurotic illness. It has been very revealing in my studies of functional disorders of the gastrointestinal tract to find how often they are associated with disturbances in the sexual sphere.

Here we touch upon the fourth problem, in which studies are just beginning to be made, that is, the possible relationship of psychological disturbances to structural alteration. The viewpoint of disease bequeathed to us from the nineteenth century, which has been described earlier in the paper, could be indicated in the following formula:

cellular disease—structural alteration—physiological (or functional) disturbance

In the twentieth century this formula underwent alteration in some situations. For example in essential hypertension and vascular disease the formula could be altered to read:

functional disturbance—cellular disease—structural alteration

We are still in the dark as to what may precede the functional disturbance, as in the example just cited of essential hypertension and the resulting vascular disease. May it not be that future investigations will permit us, in some cases at least, to say that it is possible (among other causes) for a psychological disturbance to antedate the functional alteration? Then the formula would read:

psychological disturbance—functional impairment—cellular disease—structural alteration

The following case may illustrate my meaning.

A white man of 55 was referred to me from the bronchoscopic department of Temple University Hospital, February 1933, with the diagnosis, established by esophagoscopy and roentgen-ray, of preventriculosis, generally spoken of as cardiospasm. He was receiving treatments in the form of esophageal dilations.

The patient gave the usual medical history of this condition. He stated that his illness began about 8 or 10 years before and had been progressive. He had consulted many physicians. Discouraged, he had invested a large sum of money with an osteopath who had promised cure, finally, very sick and without funds, he had come to the hospital. The previous medical history did not seem to bear upon this illness.

His life situation, however, was interesting. He had been "born into the drug business" and had never known anything except the long hours and tedious work of an under-paid pharmacy clerk. He married young and five children came in rapid succession. It was a great financial struggle to look after them. About 1916 or 1917 while working very hard he had "some kind of a breakdown" during which there were nervous symptoms and he took bromides. In 1922 his oldest and favorite son, then aged 20, had just obtained an excellent job which paid well. He gave his salary to his mother and the father was overjoyed with the finally achieved prospects of economic freedom. He had always pictured a great career for this able son and had looked forward to his financial aid to help him in old age.

Without warning one morning shortly afterward he learned that this son had just secretly married. He said, "It was the greatest blow I ever received, not only because of the financial part of it but the way he did it," that is, secretly. The patient went on to say, "I felt like a child crying until its heart would break" and he placed his hand on his epigastrium to show where he felt the blow.

He could not get over this disappointment and even considered having the marriage annulled on the basis that the boy was too young to marry. It is interesting to note, however, that he, himself, had married at the same age. He harbored a great deal of resentment toward the girl's parents who, he felt, had stolen his fine son from him. It was during this period that attacks of swallowing difficulty occurred and grew more pronounced and more frequent.

A short time later further aggravation occurred. He learned that his brother in England, whom he described as a ne'er-do-well, was cheating his mother of her small legacy. He went to England, brought his mother back and she now makes her home with him. It is significant that the mother contributes her sole income to the up-keep of him and his family. In other words, while he accuses his brother of having "bled his mother" he, himself, had already borrowed money from her and now takes her weekly allowance for living expenses. His altruism in rescuing her from his ne'er-do-well brother seems questionable.

In this regard some psychic material of unconscious origin is interesting in revealing his character. He related two recent dreams. One had to do with the pulling of teeth which reminded him of an old maxim that he would lose a friend. He was very careful the following day in conducting himself so that he would not incur anybody's enmity. Then a dream followed in which he had ordered some coal and was shovelling it in the back yard when he suddenly discovered that there was a mountain of coal which belonged to him and in the dream he said to himself, how foolish of me to be purchasing this coal when I have a whole mountain of it here that belongs to me. He had been thinking prior to the dream of whether it was necessary to purchase coal to last out the winter and wanted to avoid doing so because of his stringent financial condition. He recognized the mountain of coal as representing a lot of money and in connection with it discussed the possibility of inheriting his mother's legacy. This gives even a better understanding of his attitude toward his mother and his fear that he would lose a friend (from the dream before).

The picture we get is that of a meek, submissive and dependent individual who had always worked hard without achieving success, strongly identified with his oldest son in whom he hoped to achieve the success denied himself. With his son's secret marriage came a tremendous disappointment from which he could not recover.

An interesting commentary in line with my thesis is his experience with the osteopath. He consulted him about December 1931 and was charged \$1000, which his sons had to borrow, "for the management of his case." It is interesting to consider why he felt like investing this great sum of money with the osteopath. He says "the osteopath told me that my trouble was due to a spasm arising from a shock" and the patient went on to say to me "he did not know about my son's marriage." He was much impressed by this diagnosis "because it was the first time that any doctor had suggested that shock and worry might be responsible for my trouble." He thereupon placed his entire confidence and all the money that he could raise in the osteopath's hands.

In the recital to me, accompanied by great emotion, this poor druggist made the following significant and perhaps revealing statement: "My son's marriage was a bitter pill that I could not swallow." And who can say that that was not, at least, one meaning of the illness?

I am not going to concern myself here with the question of pathogenesis in this case, nor is that the only problem that I have left untouched, even if you agree with me in the general idea that the illness is due to the disturbance in the emotional life. Why would this situation produce such an illness in this man and probably not in another? Why did it affect the gastrointestinal tract and particularly the lower end of the esophagus? These are questions upon which much light might be thrown by psychologic studies aimed at the deeper levels of the personality and having to do with unconscious mental forces, only hints of which are contained in this report. Such studies would necessitate the psychoanalytic method, the application of which to the problem of the organ neuroses is a vast subject the surface of which has only been scratched as yet.

The point of the above remarks can be briefly stated. The study and treatment of illness constitutes much more than the investigation and eradication of disease. And yet there is nothing new or startling in this viewpoint. We have heard a great deal in recent years about the study of the organism-as-a-whole but it seems to me that we have been paying only lip service to this concept. We have been led to believe that the art of the physician (having to do with his common sense or intuition) as opposed to his science, is sufficient to grasp the problems that we have been considering. It is not enough. A real understanding of mental mechanisms is necessary in order to study the emotional life in relation to ill health. In other words the physician must be able to define the specific mental factors producing the illness, rather than to be satisfied with vague generalizations about "neurogenic background." Just as we would criticize the physician of today who would call all fevers malaria, so we must criticize the physician of tomorrow who hints vaguely at nervous factors in the background of an illness and makes no effort to really understand the psychic situation.

In his "History of Medicine" Garrison states that the fundamental error of medieval medical science, as originally pointed out by Guy de Chauliac and elucidated by Allbutt, was in the divorce of medicine from surgery. He might have added that the fundamental error of modern medical science has been in the divorce of both from psychiatry.

THE USE OF VERODIGEN (A DIGITALIS GLUCOSIDE) IN CARDIOVASCULAR DISEASE, ITS BIOLOGICAL ASSAY, AND PHARMACOLOGICAL ACTION [†]

By W D STROUD, F A C P, A E LIVINGSTON, A W BROMER,
J B VANDERVEER and G C GRIFFITH,
Philadelphia, Pennsylvania

INTRODUCTION

THOSE who have assayed digitalis by any of the recognized biological methods are well aware of the difficulties encountered, and those who prescribe assayed products are frequently confronted with uncertain results. Consequently, any stable digitalis preparation producing the desired therapeutic effects and at the same time being sufficiently uniform in its action not to require a biological assay, would be greatly appreciated. From the long list of digitalis preparations on the market it is evident that no such ideal substance is available at the present time.

According to many reports, verodigen has been used in Europe for a number of years with apparently good clinical results, but is not generally known in this country, and certainly has not been used to any considerable extent.

After five years of clinical observation, Straub and Krehl¹ concluded that "everything that can be attained with digitalis will also be attained quickly, safely and in a suitable manner with verodigen." Furthermore, they state that "after four to five days it can usually be discontinued, because in favorable cases the ventricular as well as the arterial pulse rate will automatically become constant." In view of these claims, particularly the latter, there seems to be reason to wonder whether this special glucoside preparation has received sufficient biological and clinical study to warrant its being accepted without further question as a substitute for whole leaf preparations of digitalis. With these facts in mind, it seemed that verodigen, though not a definite chemical substance, possessed biologic properties which deserved to be more carefully investigated.

Verodigen was first isolated in 1912 by Kraft² who called it Gitalin. He was of course familiar with the previous methods of Schmiedeberg³ who prepared digitoxin in a pure crystalline form and found it to be practically insoluble in water.

Straub and Krehl¹ concluded that verodigen is a mixture which must contain not more than 5 per cent of ineffective substances. They also reported on several phases of its pharmacological action and concluded that it possessed all those properties which can be ascribed to digitalis substances in general, such as slowing the pulse, increasing the activity of the heart.

[†] Read at the Chicago meeting of the American College of Physicians, April 19, 1934. From the Robinette Foundation and the Graduate Hospital of the University of Pennsylvania in part under the Morris W. Stroud Jr. Fellowship in Cardiology, and from the Department of Pharmacology of Temple Medical School.

musculature, and altering the electrocardiogram. They also considered it superior to other digitalis glucosides in so far as its absorption is concerned, and believed its rate of elimination to be such as to produce the optimum degree of accumulation.

Mansfeld and Horn⁴ compared verodigen with a 0.5 per cent infusion of digitalis leaves and concluded that 0.8 mg of verodigen is equivalent to 100 mg of leaf. The same authors used isolated frog hearts, weakened by perfusion with a solution containing only one half the proper concentration of calcium. These hearts were restored by the use of verodigen in a manner similar to that seen after the use of digitalis infusions.

RESULTS OF BIOLOGICAL ASSAY AND PHARMACOLOGICAL STUDY

The tablets which contain verodigen for clinical purposes are composed largely of inert material to make them of proper size and may vary slightly in weight. They do not form a perfectly clear preparation in small volumes of sodium chloride solution as required for assay purposes. For these reasons the verodigen powder has been used in these experiments instead of the tablets.*

This powder has been found to be a white amorphous substance which readily dissolves in about 600 parts of cold water or salt solution, provided it is first thoroughly triturated with only a small amount of the solvent. It is also readily soluble in chloroform, ether, and alcohol. No definite melting point could be found, though all of it becomes a brownish liquid at less than 120° C. Fresh solutions, purposely made from the contents of one bottle, have been used in all cases included in this report, and hence no statement can yet be made concerning the uniformity of various lots or its stability in solution.

Frog Assay Assayed by the U. S. P. X one hour frog method, this material yields results which show about the same degree of variation as do those yielded by other digitalis preparations. By this method 0.0005 mg of ouabain, used as the standard, is the average minimal lethal dose per gram of normal frog. In a typical series of 35 frogs used in the present experiments, the average minimal lethal dose was 0.00045 mg of ouabain, or 90 per cent of the dose for normal frogs. Verodigen, administered in the same manner to a series of 45 frogs of the same lot, shows an average minimal lethal dose of approximately 0.0045 mg per gram, which would correspond to 0.005 mg per gram of normal frogs. If powdered digitalis leaves are of standard potency, the average minimal lethal dose is 0.6 mg per gram. It therefore follows according to this method, that verodigen has 120 times the potency of standard digitalis leaves. Mansfeld and Horn obtained a corresponding figure of 125.

Cat Assay Verodigen has also been assayed on one series of cats by the modified Hatcher's cat method of de Lind van Wijngaarden as recommended by Burn.⁵

* Merck & Co., Inc., kindly supplied the material for these experiments and the tablets used in the clinical study.

This method specifies that a 0.5 per cent aqueous extract of digitalis powder be used, and that the rate of intravenous injection from a burette be about one cubic centimeter per minute, adjusted so that death will occur in not less than 30 and in not more than 55 minutes. Artificial respiration is also specified, but in the present report artificial respiration has not been used in any case. Ether anesthesia was adjusted so that corneal reflexes were just negative, and special care taken to prevent obstruction of the trachea by mucus. Respiratory rate and depth remained good up to the time when the blood pressure fell to zero, which usually takes place suddenly.

In these experiments a 0.005 per cent solution of verodigen in salt solution was compared with a 0.5 per cent aqueous infusion of a standardized digitalis powder,* 0.85 gram of which was equivalent to one gram of the international standard. The results are shown in tables 1 and 2.

It will be noted that when a 0.5 per cent infusion of the equivalent of international standard powder was used in eight cats the average lethal dose per kilogram was 17.14 c.c. The average deviation from this average was 2.6 c.c. The "standard deviation" calculated according to Burn⁵ is 3.13 and is a measure of the amount of variation in the individual figures. According to Burn we may determine how far the average is likely to vary when different groups are used. His formula applied to the present series gives 1.4 as the "standard deviation of the average" and means that if other groups of cats are used the value obtained will vary from the true value less than 1.4 in two out of three groups, and more than 1.4 in one out of three groups.

TABLE I
Standard Digitalis Powder

| Cat No | Sex | Minutes required to kill | Wt of cat in kilos | C c of 0.5% infusion of standardized powder required to kill | Equivalent to c c of 0.5% infusion of international standard powder | C c per kilo of 0.5% infusion of international standard powder required to kill | Deviation from average |
|---------|-----|--------------------------|--------------------|--|---|---|------------------------|
| 114 | F | 68 | 2.75 | 50.5 | 59.4 | 21.7 | 4.56 |
| 107 | F | 43 | 2.95 | 39.0 | 45.9 | 15.6 | 1.56 |
| 118 | F | 41 | 3.2 | 32.5 | 38.2 | 11.9 | 5.24 |
| 112 | F | 42 | 3.15 | 40.5 | 47.6 | 15.1 | 2.04 |
| 111 | F | 56 | 2.64 | 48.0 | 56.5 | 21.4 | 4.26 |
| 109 | M | 53 | 3.1 | 49.5 | 58.2 | 18.8 | 1.66 |

| 108 | M | 46 | 3.25 | 47.0 | 55.3 | 17.0 | 0.14 |
| Total | | 400 | 24.07 | | | 137.1 | 21.02 |
| Average | | 50 | 3.01 | | | 17.14 | 2.6 |

"Standard deviation" 3.13

17.14 c.c. of 0.5% infusion is equal to 0.0857 Gm. of powder

"Standard deviation of the average" 1.4

* This powder was of lot 428 from the Laboratory of Hygiene, Department of Pensions and National Health, Ottawa, Canada. It was received via Sharp and Dohme through the courtesy of Dr J. C. Munch.

TABLE II

Verodigen

| Cat No | Sex | Minutes required to kill | Wt of cat in kilos | C c of 0.005% solution required to kill | C c per kg of 0.005% solution required to kill | Mg per kg required to kill | Deviation from average |
|---------|-----|--------------------------|--------------------|---|--|----------------------------|------------------------|
| 64 | M | 33 | 3.33 | 32.0 | 9.6 | 0.48 | 3.33 |
| 81 | F | 55 | 2.65 | 29.8 | 11.2 | 0.56 | 1.73 |
| 86 | M | 50 | 2.45 | 32.5 | 13.3 | 0.67 | .37 |
| 85 | F | 52 | 1.76 | 25.5 | 14.5 | 0.73 | 1.57 |
| 90 | F | 58 | 2.78 | 33.0 | 11.8 | 0.59 | 1.13 |
| 73 | F | 58 | 2.32 | 40.0 | 17.2 | 0.86 | 4.27 |
| Total | | 306 | 15.29 | | 77.6 | 3.89 | 12.40 |
| Average | | 51 | 2.55 | | 12.93 | 0.65 | 2.666 |

"Standard deviation" 2.46

"Standard deviation of the average" 1.21

0.00065 Gm verodigen is equal to 0.0857 Gm International Standard Powder

Therefore potency of verodigen is 132 times International Standard Powder

The same calculations applied to a 0.005 per cent solution of verodigen in six cats give an average lethal dose of 12.93 c c per kilogram, with a "standard deviation" of 2.46 and a "standard deviation of the average" of 1.21. These deviations are somewhat less than the corresponding values for the standard digitalis powder, and might be interpreted as due to a product having a more uniform action, or it may be due to the fact that verodigen is used here in a more potent concentration.

If 12.93 c c of a 0.005 per cent solution of verodigen are equal in potency to 17.14 c c of a 0.5 per cent solution of international standard digitalis powder, then verodigen is 132 times as potent as the digitalis powder. If Hatcher's figure of 0.1 mg of ouabain and the present figure of 0.65 mg of verodigen are accepted as the lethal doses per kilogram of cat, then ouabain, while not a digitalis preparation, is 6.5 times as potent on the cat's heart as verodigen.

Stability During the summer of 1932 seven cats were given various doses of verodigen intravenously under ether anesthesia. At that time interrupted injections were made from a syringe instead of a constant infusion from a burette. As compared with the assay tests on cats, as mentioned above, these earlier experiments required a much longer time and correspondingly lower lethal doses were obtained (table 3). No standardized digitalis powder being on hand at that time, no comparisons with digitalis were made. Recently it seemed advisable to repeat these experiments as nearly as possible, using verodigen powder from the same bottle which had been kept at room temperature and frequently opened, in order to determine whether any deterioration could be detected. The results thus obtained on four cats are shown in table 4, and are to be compared with the results previously obtained on seven cats as recorded in table 3.

TABLE IV

Verodigen (Twenty months after Table 3)

| Date | Cat No | Sex | Wt in kg | Total dose and how given | Minutes required to kill | Mg per kg required to kill |
|---------|--------|-----|----------|---|--------------------------|----------------------------|
| 4/2/34 | 136 | M | 3 13 | 18 × 0 1 mg at 6 minute intervals | 119 | 0 58 |
| 4/2/34 | 139 | M | 3 46 | 1 0, 0 6, 0 3 mg at 40 minute intervals | 103 | 0 29 |
| 4/3/34 | 123 | M | 3 74 | 0 5, 0 5, 0 3, 0 2 mg at about 30 minute intervals | 137 | 0 40 |
| 4/3/34 | 135 | M | 3 5 | 0 5, 0 5, 0 3, 0 1, 0 1, 0 1, 0 1 mg at about 30 minute intervals | 190 | 0 49 |
| Total | | | 13 83 | | 548 | 1 76 |
| Average | | | 3 45 | | 137 | 0 44 |

The average lethal dose per kilo recently obtained is 0 44 mg as compared with 0 43 mg obtained about 20 months previously. The average time required to produce death in the two groups is also essentially the same. These results indicate that no appreciable change in potency has taken place in this lot of verodigen powder during a period of about 20 months.

Attention is called here to the marked difference between average lethal doses of verodigen obtained by different methods. The de Lind van Wijn-gaarden method, by specifying that the rate of injection should be such as to produce cardiac arrest in 55 minutes or less, requires an average of 0 65 mg per kilo, whereas, if a period of 137 minutes is allowed, an average of only 0 44 mg is sufficient to produce death. This should serve to emphasize the importance of following the same method when comparisons are to be made between verodigen and any other material such as standard powder.

Effect on Pulse Rate Experiments on verodigen other than those concerned with assay determinations are now in progress, and in a few such cases results can now be stated

In various experiments on dogs and cats under ether anesthesia, a prompt and pronounced slowing of the pulse rate has been observed after intravenous injection of verodigen. If the dose is increased, the pulse becomes rapid and usually reaches a point, before death of the animal, which exceeds the normal rate. During this period of rapid heart action the pulse becomes irregular and finally ceases with the blood pressure falling to zero. This train of events corresponds to that during a similar injection of an aqueous extract of standard digitalis powder.

Effect on Isolated Frog Hearts When verodigen is perfused through an isolated frog heart the character of the effect produced is typical of digitalis action. Figure 1 illustrates such an effect as compared with that of ouabain. The heart promptly shows a more powerful contraction, which is soon accompanied by a diminished relaxation. The improvement in contractions is more pronounced in hearts which have already become weakened. The diminished diastole gradually progresses until the heart stops in systole.

FIG. 1. The character of records obtained on isolated frog hearts by digitalis preparations. In this case ouabain and verodigen are compared.

In the experiments illustrated, the drop record from the aorta does not show an increased output in either case, although in other experiments where the action progresses less rapidly an increased output may sometimes be observed. In one experiment the output was 40 drops of Ringer's solution per minute immediately preceding the application of verodigen, increased to 52 drops during the third minute of perfusion with Ringer plus verodigen and then gradually diminished as diastole diminished.

Electrocardiographic Findings Electrocardiographic records taken on dogs after the administration of verodigen by mouth, and compared with similar records taken after the administration of digitalis leaves, show conclusively that verodigen is capable of producing a typical digitalis-like inversion of the T-wave (figure 2). At about the same time the dogs were

FIG 2 The inversion of the T-wave in two dogs, one of which had verodigen and the other digitalis

observed to salivate profusely, vomited, and sometimes refused food. The dose of verodigen required to elicit these symptoms was approximately 0.18 mg per kilo per day for a week. Previous to this time doses of one half this amount per day for 10 days or more had failed to produce any obvious effect.

The corresponding amount of digitalis leaves required to produce similar results was approximately 60 mg per kilo per day. It should be stated, however, that this particular lot of powdered leaf has not been assayed recently and may prove to be somewhat below the standard potency. Different dogs, or the same dog on different days, may show some variation electrocardiographically which makes caution necessary when drawing conclusions from this animal.

Absorption In one dog with a Thiry-Vella fistula 0.55 mg of verodigen per kilo introduced directly into the loop of small intestine without an anesthetic produced vomiting in 33 minutes. The pulse rate fell from 105 to 80 per minute in the same time. During the next hour vomiting occurred

five times, the pulse rate increased to 110 and became very irregular. During the next hour no changes occurred and further observations were not made. This was one of the early experiments and from later observations these symptoms would indicate the prompt absorption of an almost fatal dose.

When the lethal dose of verodigen, calculated on the basis of 0.65 mg per kilo, is given to cats by stomach tube they commonly vomit within 30 minutes and show no further marked symptoms. In a series of eight cats 80 per cent of the lethal dose, calculated in the same manner, was introduced directly into the lumen of the small intestine without a general anesthetic by opening the abdomen under local cocaine anesthesia. A syringe with large needle was used for injecting into the intestine and aseptic precautions were observed. All of these animals vomited, usually in about two hours, and one died during the following night, which indicates that verodigen is readily absorbed from the small intestine of cats. This method also shows that the vomiting is not due to local gastric irritation, unless we assume that it is regurgitated into the stomach, or eliminated into the stomach from the circulation.

Four of these cats were given verodigen the next day, in the same manner as used in the assay experiments, and required an average of only 0.37 mg per kilo instead of 0.65 as would probably have been required without the intestinal dose, thus indicating that approximately one half the effect from the intestinal dose was present the next day, after administration.

CLINICAL STUDIES

Method of Procedure Five patients with established auricular fibrillation, one patient with auricular flutter and two patients with regular sinus rhythm, presenting severe congestive failure, none of whom had taken digitalis previously, were studied on the wards of the Pennsylvania Hospital and the Graduate Hospital of the University of Pennsylvania. Also, 14 ambulatory patients with established auricular fibrillation, previously controlled with whole leaf preparations of digitalis or with Digalen,*⁷ were changed to verodigen and followed in the Out-Patient Department of the Pennsylvania Hospital. In four cases, the administration of digitalis was stopped for a period of two to four weeks immediately preceding the giving of verodigen. The drug was administered by mouth in tablets of 1/240, 1/160 or 1/80 grain each. Each out-patient was examined every week or two, at which time a vital capacity determination and an electrocardiogram were also made.

Results In the five cases of established auricular fibrillation, previously untreated with digitalis, verodigen brought about slowing of the ventricular rate, with elimination of pulse deficit, and marked clinical improvement after a total dosage of 1/16 to 1/10 grain as shown in table 5. Similarly, the

* The clinical courses of these patients had been followed carefully from December 1931 to the time of the present investigation, in a comparison of the therapeutic efficacy of Digalen with that of two whole leaf digitalis preparations.

two patients with regular sinus rhythm in severe congestive failure showed definite clinical improvement with that dosage distributed over five and eight days respectively (See reports of Cases 20 and 17, with figures 3 and 4)

FIG 3 Case XX J G, aged 49, with arteriosclerotic hypertensive heart disease, marked cardiac enlargement and congestive failure Verodigen started after 24 hrs of bed rest Diuresis occurred on the fifth day after a total dosage of 1/16 gr Black and white sections indicate fluid intake and the vertical lined sections, the urinary output

FIG 4 Case XVII G C, aged 54, with arteriosclerotic hypertensive heart disease marked cardiac enlargement and congestive failure Verodigen started after 10 days of bed rest with but little improvement during rest period Diuresis occurred on eighth day after a total dosage of 1/10 gr Black and white sections indicate fluid intake and the vertical lined sections, the urinary output

† Death occurred, January 4, 1934, the result of a mesenteric embolism

CASE XX

J G, an Italian male, aged 49, was admitted to the Pennsylvania Hospital, August 22, 1933, complaining of shortness of breath of six months' and edema of the legs of three months' duration. Swelling of the abdomen and orthopnea had been present for the past few days only. He had received no treatment prior to admission.

Physical examination revealed marked orthopnea and engorgement of the neck veins. The heart rhythm was regular, rate 96. The heart was enlarged almost to the anterior axillary line in the fifth interspace. A systolic murmur was audible at the apex. Moist râles were present at the lung bases, the liver edge was palpable 5 cm below the costal margin in the right mid-clavicular line, there was slight ascites, and moderate pitting edema of the lower extremities and of the lower portion of the trunk. There was moderate arteriosclerosis of the palpable vessels. Blood pressure 164/100.

On the second day after admission, the administration of verodigen was begun. On the fifth day, after having received 6 tablets of 1/80 grain each, there occurred marked diuresis (which persisted for several days), a marked slowing of the rate, and a change in the T-wave of the electrocardiogram. A daily dose of 1/80 grain was given thereafter. The patient had been up and about the ward, free from all signs of congestive failure, for 4 weeks, until October 21, when nausea and vomiting occurred.

Coupled rhythm, with ventricular premature contractions, was noticed November 21, four weeks after the administration of verodigen had been stopped, and persisted intermittently until discharge from the hospital December 30, 1933. The patient was sent home, without medication, to be followed in the Cardiac Clinic, but failed to return as advised.

Cardiovascular Diagnosis A—Arteriosclerosis, hypertension, B—Cardiac enlargement, myocardial fibrosis, mitral insufficiency, C—Regular sinus rhythm, D—Class III on admission and Class 2b on discharge from the hospital.

CASE XVII

G C, a colored male, aged 54, was admitted to the Pennsylvania Hospital, October 9, 1933, complaining of shortness of breath, swelling of the legs and fullness

in the epigastrium of two weeks' duration. Previously, he had been in fairly good health, with the exception of "asthmatic attacks" in the early fall of recent years.

On physical examination, he appeared older than the stated age. There was marked generalized arteriosclerosis, with marked cardiac enlargement and moderate orthopnea. The heart rhythm was regular, rate 116. A systolic murmur was audible at the apex. Moist râles were present at the lung bases, the liver was enlarged and tender, 9 cm. below the costal margin in the right mid-clavicular line, there was moderate ascites and pitting edema of the lower extremities. Blood pressure 165/100.

During the first 24 hours in the hospital, he was given 9 grains of powdered digitalis leaves, and then, during the next nine days, no digitalis was prescribed. At the end of that period, in spite of rest in bed, the signs of congestive failure remained practically unchanged.

On October 19, the administration of verodigen was begun. A dose of 1/80 grain was given daily until November 3. On the eighth day of this regimen, after a total of 1/10 grain of verodigen had been given, there occurred marked diuresis, which persisted for several days, with a loss of 14½ pounds in weight. Simultaneously, definite changes in the T-waves of the electrocardiogram, indicative of a digitalis effect, were present. By November 2, all signs of congestive failure disappeared, and the patient was up and about the ward without any noteworthy subjective symptoms. On November 3, a daily dosage of 1/240 grain was instituted, and was continued until his discharge from the hospital, November 21, 1933.

On January 9, 1934, he came to the receiving ward of the hospital, in extreme congestive failure, irrational and incontinent. He had failed to return to the Cardiac Out-Patient Clinic, as advised, but had returned to work and had not taken any medicine. Verodigen was administered again, but bronchopneumonia developed, and death occurred on the seventh day after admission.

Cardiovascular Diagnosis A—Arteriosclerosis, hypertension, B—Cardiac enlargement, myocardial fibrosis, mitral insufficiency (relative), C—Regular sinus rhythm, D—Class III.

CASE XXI

C. J., a negro male, aged 54, was admitted to the Pennsylvania Hospital, February 20, 1934, acutely ill, with dyspnea, palpitation and cyanosis. During the past 10 years he had suffered four attacks of palpitation with rapid heart action, associated with dyspnea and precordial pain. The duration of the attacks varied from one to 24 hours. For the past three years he had noticed shortness of breath on exertion, and, about three weeks immediately preceding admission, he began suffering marked dyspnea and tachycardia, which had grown worse gradually, with a productive cough superimposed.

Physical examination revealed orthopnea, with Cheyne-Stokes respiration and engorgement of the neck veins. The left border of the heart was in the anterior axillary line in the fifth interspace, the rhythm was regular, the rate was 170 per minute, no murmurs were audible. The radial pulse was barely perceptible. The edge of the liver was palpable 3 centimeters below the costal margin in the right midclavicular line, there were numerous moist râles at both lung bases, there was no edema of the extremities. Blood pressure 110/96. An electrocardiogram, shortly after admission, showed auricular flutter with a 2:1 auriculoventricular block.

Verodigen was given in dosage of 1/80 grain, twice daily. After four days there was improvement in his general condition, but practically no change in the heart rate. On the thirteenth day, nausea and vomiting occurred, and, therefore, the administration of verodigen was stopped. The next morning auricular fibrillation was present with a ventricular rate of 100 per minute, and the general condition of the patient was greatly improved. During the next six days no medication was given, and there occurred a gradual increase in the heart rate to 140–150 per minute, with an increasing

pulse deficit Quinidine sulphate was then prescribed On the third day of quinidine therapy, auricular flutter with 2:1 block recurred, and the patient went into a state of shock with Cheyne-Stokes respiration The administration of quinidine was stopped, and verodigen was resumed (1/80 grain, twice daily) Two days later the degree of block had changed to 3:1 and 4:1, and after another two days auricular fibrillation returned At present the patient is up and about the ward without any subjective or objective signs of circulatory insufficiency, even though auricular fibrillation persists,

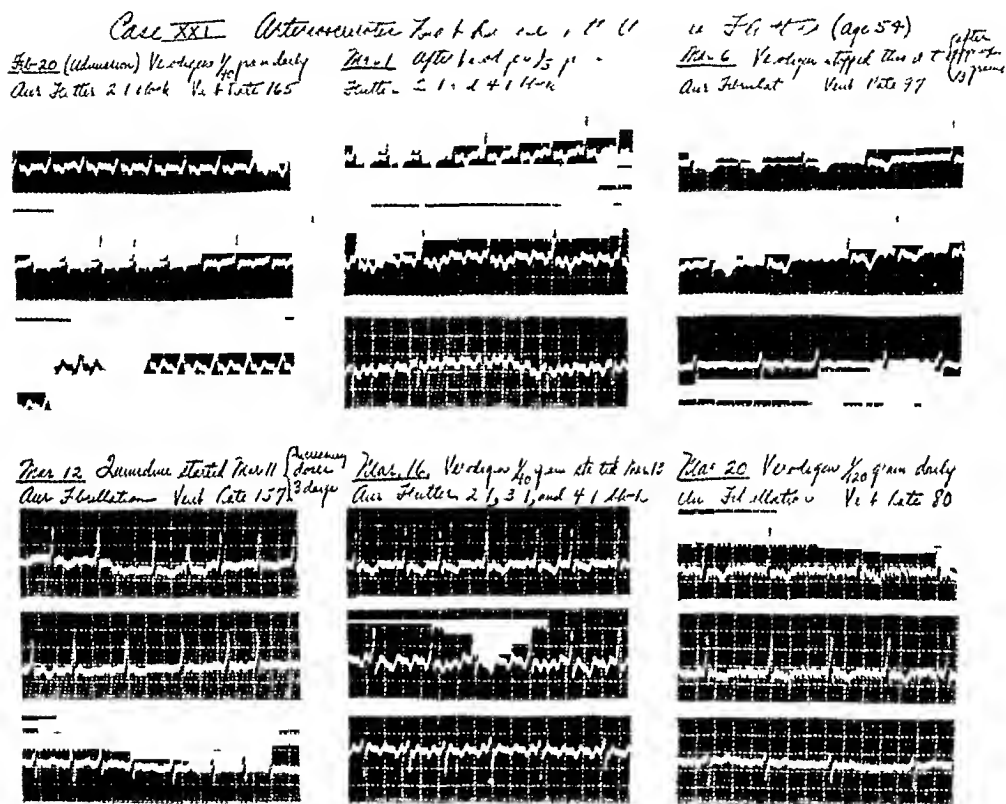

FIG 5

with a ventricular rate of about 80 per minute, with a maintenance dose of 1/240 grain of verodigen, twice daily

Cardiovascular Diagnosis A—Arteriosclerosis, B—Cardiac enlargement, myocardial fibrosis, C—Auricular fibrillation, paroxysmal auricular flutter, D—Class 2b

In the first two of the above cases changes in the T-wave of the electrocardiogram, characteristic of digitalis action, occurred simultaneously with the clinical betterment, and marked diuresis was occasioned in these cases with edema and ascites

The patient with auricular flutter and myocardial insufficiency showed a change to auricular fibrillation under the administration of verodigen, and then when medication was stopped the fibrillation reverted to flutter On resuming the administration of verodigen, fibrillation was again established

and controlled at a rate within normal range with a dose of 1/240 grain, twice daily

In 14 ambulatory patients with established auricular fibrillation, given verodigen,—after having been previously controlled for many months with whole leaf preparations of digitalis or with Digalen,—it was found that the state of optimum digitalization could be maintained without difficulty (table 6)

An abstract of three typical cases of those included in table 6 follows

CASE XIII

B P, an Italian housewife, aged 49, made her first visit to the Cardiac Clinic of the Pennsylvania Hospital in 1924, presenting signs and symptoms of mitral stenosis and marked cardiac enlargement. Auricular fibrillation has been present since her admission to the hospital, with severe congestive failure, January 1928. Since then, she has been taking digitalis regularly. There has been a gradual diminution of her circulatory efficiency, with increasing hepatomegaly, and recently the spleen has become palpable. In spite of the cardiac handicap, she is still able to do some light housework.

Cardiovascular Diagnosis A—Unknown, B—Cardiac enlargement, mitral stenosis and insufficiency, C—Auricular fibrillation, established, D—Class 2b

Her clinical course, immediately before and during the administration of verodigen has been as follows

| Brand of digitalis | A H A | | Verodigen | | | | | |
|-----------------------------|---------|---------|-----------|--------|-----------------|---------|---------|---------|
| Date | 5/4/33* | 5/18/33 | 5/25/33 | 6/1/33 | 6/8/33 | 8/24/33 | 1/25/34 | 3/22/34 |
| Av daily dose (gr) | 1½ | 0 | 1/280 | 1/140 | 1/280 | 1/280 | 1/240 | 1/240 |

| Vital capacity (c c) | 2100 | 2100 | 2200 | 2100 | 2100 | 2200 | 1970 | 2100 |

* For 7 months immediately preceding May 4, 1933, this patient had been taking digitalis prepared by the American Heart Association, gr 1½, daily. On that date, she was changed to verodigen, and the next day she took two tablets, 1/80 grain each. At 5 00 a m, the morning immediately thereafter, she was awakened with vomiting and dizziness, which kept her in bed for nine days. While bed-ridden, she took no verodigen, but later on, took one tablet daily, the five days just before her next clinic visit, May 18, 1933.

CASE VIII

M K, a Hebrew salesman, aged 40, presented aortic insufficiency, mitral stenosis and insufficiency, moderate cardiac enlargement, and regular sinus rhythm on his first visit to the Cardiac Clinic of the Pennsylvania Hospital, November 1927. In August 1930, he suffered sudden loss of power in the left arm, leg and face, without loss of consciousness or speech, and two weeks were spent in another hospital. On his next visit to the Cardiac Clinic in December 1930, weakness of the left arm was the only residual finding, but auricular fibrillation was present, with a ventricular rate of 144 and a pulse deficit of 30 per minute. There were no signs of congestive failure, but he complained of palpitation and dyspnea on slight exertion. Since that time he has been taking digitalis regularly. On three different occasions, embolic phenomena have occurred in the spleen, brain and kidney, respectively, with good recovery in each instance.

Cardiovascular Diagnosis A—Rheumatic fever, B—Cardiac enlargement, aortic insufficiency, mitral stenosis and insufficiency, C—Auricular fibrillation, established, D—Class 2b.

His clinical course, immediately before and during the administration of verodigen, has been as follows:

| Brand of digitalis | B W & Co | Verodigen | | | | | |
|--------------------------|-------------|-----------|---------|---------|----------|--------|--------|
| Date | 4/20/33* | 6/15/33† | 6/29/33 | 7/27/33 | 10/26/33 | 1/4/34 | 3/1/34 |
| Av daily dose (gr) | 3 | 1/160 | 1/240 | 1/240 | 1/240 | 1/240 | 1/240 |
| Weight (lbs) | 164 | 162 | 162 | 160 | 160 | 160½ | 166½ |
| Ventricular rate | 72 | 88 | 78 | 66 | 84 | 96 | 76 |

* A daily dose of 3 grains of Burroughs, Wellcome & Co's digitalis had been taken for six months prior to this date.

† Administration of verodigen started on this date.

CASE IV

S F, a Hebrew male, 32 years of age, complained of rapid heart action of three months' duration, with fatigue, dyspnea on exertion and cough, on his first visit to the Cardiac Clinic of the Pennsylvania Hospital, June 1931. At the age of 15 years, he had been told that he had a heart murmur, however, he had enjoyed excellent health and had been very active physically previous to 1931. Physical examination revealed cardiac enlargement, mitral stenosis and insufficiency, and auricular fibrillation, without any signs of congestive failure. Since that time he has been taking digitalis regularly.

Cardiovascular Diagnosis A—Unknown (tonsillitis), B—Cardiac enlargement, mitral stenosis and insufficiency, C—Auricular fibrillation, D—Class 2a

His clinical course, immediately before and during the administration of verodigen, has been as follows

| Brand of digitalis | Digalen | | Verodigen | | | | |

| Vital capacity (c. c.) | 2600 | 2600 | 2150 | 2600 | 2600 | 2600 | 2100 |

* Digalen, gr. 1½ daily, had been taken for a period of 8 months prior to this date. All medication was stopped on this date.

† Administration of verodigen, gr. 1/160 daily, started on this date.

In view of the potency of the preparation, it was administered to the first few patients most cautiously. Through careful check of the dosage necessary to produce therapeutic or toxic effects, it was found clinically that 1/240 grain was the approximate equivalent of 1½ grains of whole digitalis leaves (one cat unit). This figure represents a potency three times as great as that reported in the European literature (in which 1/80 grain has been termed the equivalent of 1½ grains of whole digitalis leaves).

Overdosage with verodigen produced toxic effects similar to those which might be precipitated by whole leaf preparations. In spite of the caution which attended the administration of the preparation before the approximate cat unit strength was determined, nausea and vomiting were occasioned in a few instances. In one of the two patients with regular sinus rhythm (Case 20), coupled rhythm occurred with nausea and vomiting.

DISCUSSION

The present cat assay results show verodigen to be 132 times as potent as digitalis leaf, and the frog method gives a corresponding figure of 120

These agree with a similar figure of 125 found by Mansfeld and Horn

In the present clinical studies verodigen, in doses of 1/240 of a grain, is found to produce results corresponding to 1½ grains of digitalis leaf—a ratio of 360 to 1 or nearly three times that shown biologically. This is a higher clinical potency than formerly recognized and may explain the tendency, as encountered by some cardiologists, to produce vomiting.

By the cat assay method, digitalis infusions and verodigen are both injected intravenously and hence the effect does not depend on absorption. As used clinically by mouth, if verodigen is more readily or more completely absorbed than digitalis, it would show a higher potency than digitalis. The difference, therefore, in potency as shown by the biological and clinical observations, may prove to be due to a difference in absorption. Also it must be borne in mind that there exists in the majority of patients with established auricular fibrillation a fairly wide margin between the minimum dosage necessary for optimum digitalization and the maximum dosage which can be tolerated without the incidence of toxic effects, which fact might explain in part the difference in biological and clinical observations. Furthermore, as suggested by Mansfeld and Horn, the higher potency of verodigen clinically than by the frog assay may be due to the higher temperature of man.

SUMMARY AND CONCLUSIONS

I Verodigen biologically

- 1 Is about 130 times as potent as dry standardized digitalis leaf
- 2 Slows the heart of cats and dogs as does digitalis
- 3 Inverts the T-wave of the electrocardiogram of dogs
- 4 Is promptly absorbed from the small intestine of cats and dogs
- 5 When so absorbed in large doses, about 50 per cent of the effect is present the next day
- 6 Produces vomiting which, in cats and dogs, is not due to local gastric irritation
- 7 Stops frog hearts and cat hearts in systole
- 8 As non-desiccated powder, at room temperature, is stable 20 months or more
- 9 Is soluble in water, bitter to taste, and has no definite melting point

II Clinical study

1 A clinical study of the therapeutic efficiency of verodigen—the *gitahn* glucoside of digitalis—has been made upon (a) five patients with established auricular fibrillation and one patient with auricular flutter, previously untreated with digitalis, (b) two patients with regular sinus rhythm and advanced congestive heart failure, (c) fourteen patients with established auricular fibrillation, previously controlled with whole leaf digitalis preparations or Digalen.

2 Verodigen was found (a) to control the ventricular rate in established auricular fibrillation, (b) to produce clinical improvement, with marked diuresis, in patients with congestive heart failure and regular sinus rhythm, and (c) to produce in the electrocardiogram S-T interval and T-wave changes, characteristic of digitalis action

3 Careful clinical observation revealed 1/240 gram of verodigen to be equivalent to one cat unit (approximately 1½ grains of powdered digitalis leaves)

4 The total dosage necessary for optimum digitalization varied from 1/10 to 1/16 grain, administered over a period of five to six days

5 The most frequent adequate maintenance dose of verodigen was 1/240 grain daily

6 Toxic effects from overdosage with verodigen were similar to those produced by whole leaf digitalis preparations

7 The potency of verodigen demands careful observation in its administration, especially with patients who have recently been taking any digitalis preparation

It is a pleasure to thank Dr Ernst Spiegel for taking electrocardiographic records of dogs, and Dr Ralph C Bradley for assisting in the preliminary frog assay experiments

GLYCOGEN FORMATION IN DIABETES *

By F D W LUKENS, *Philadelphia, Pennsylvania*

DURING the past two years observations on the behavior of muscle glycogen have been made by Dr C N H Long and the author¹ at the University of Pennsylvania. The breakdown and recovery of muscle glycogen, following exercise, in normal and depancreatized animals has been directly studied and certain aspects of the formation of glycogen in the absence of insulin have been analyzed. These results will be briefly outlined and their relation to our present concepts of the mechanism of glycogen regulation in diabetes will be considered.

Since muscle glycogen comprises the largest amount of carbohydrate stored in the body, one is naturally concerned with its behavior in diabetes mellitus. Disregarding for the moment the small amounts of glycogen in the heart, kidney and skin, one may make the following summary of the glycogen content of the body. In fed animals the liver contains 6 per cent of glycogen, the muscles, 0.6 per cent. The muscle weight is more than 10 times that of the liver so that the actual quantity of glycogen is divided fairly evenly between muscles and liver. On prolonged fasting, muscle and liver glycogen diminish but not in the same proportion. Almost all the glycogen is retained by the muscles, while that in the liver is reduced to 1 per cent or often less. The fasting values are similar to those found in diabetic animals. Thus in our animals, fasted 24 hours, the normal ones had an average muscle glycogen of 727 mg per 100 gm and the diabetic of 651 mg per 100 gm, a very slight difference. No estimations were made of liver glycogen in diabetic animals but its extremely low level in such animals is an established observation. In diabetes, therefore, muscle glycogen becomes, more than ever, the chief tissue carbohydrate. It is evident that muscle glycogen is resistant to inanition or pancreatectomy in contrast to the liver which is promptly deprived of most of its glycogen under these circumstances.

From these and other such observations it is apparent that muscle glycogen is well maintained in the absence of insulin. However, only four references have been found in the literature to glycogen synthesis in diabetic animals and they disagree^{2, 3, 4, 5}. With several improvements in methods it has been possible to obtain more satisfactory results, which show directly the amount and rate of muscle glycogen formation in the absence of insulin.

There is another side to the question of glycogen synthesis. Since the discovery of insulin certain facts have been established with regard to both

* Read at the Chicago meeting of the American College of Physicians, April 18, 1934.
From the George S. Cox Medical Research Institute, University of Pennsylvania.

muscles and liver The administration of glucose raises the glycogen level in normal animals Insulin markedly increases the glycogen in diabetic animals Glucose and insulin together produce the maximum effect in both normal and diabetic animals Finally, Major and Mann⁶ have shown that merely giving glucose in large amounts to diabetic animals causes some increase in their glycogen The conclusion from this is that glycogen formation depends both on glucose concentration and on the presence of insulin Insulin affects glycogen formation, yet glycogen is formed in the absence of insulin What, then, is the relation of insulin to the process? A possible answer may be found in our direct observations upon depancreatized animals

Muscle glycogen is being built up and broken down at all times, both processes occurring simultaneously In order to study these it is necessary to interfere with the regulation or homeostasis of glycogen Exercise is the physiological means of doing this The breakdown of muscle glycogen can be so accelerated by contraction that it is readily measured The synthesis that follows can also be observed

Cats were the animals used The normal cats were fasted 24 hours before the experiments Under nembutal anesthesia both hind legs were stimulated electrically, the stimulus being the same in all experiments Immediately after stimulation one hind leg was removed, giving the glycogen level after it had been lowered by muscular contraction At the end of the recovery periods of one, two and six hours respectively, the second hind leg and a foreleg were removed for glycogen determination The technic of removal and glycogen determination has been described previously⁷ The difference between the second hind leg and the first measured the quantity of glycogen laid down during the recovery period Since resting glycogen values fluctuate considerably in the cat, and since the glycogen breakdown varies even with a constant stimulus, a resting level for the individual animal was desired This was necessary so that the amount lost during stimulation might be calculated and so that the amount recovered might be related to the amount lost For this purpose the foreleg, which was not stimulated, was taken It was found that because of its increased connective tissue the foreleg glycogen was lower than that of the hind leg, but on a number of control cats, both normal and diabetic, this was found to be a very constant difference, so that we had no hesitation in using this ratio to calculate the resting values This difference between the resting value and the value after exercise gave the amount of glycogen lost during stimulation

The diabetic cats were depancreatized one to three weeks before the experiments They were maintained on insulin until recovery from operation was complete Insulin was withdrawn 48 hours, and food 24 hours, before the experiments, which were conducted in the same manner as those on the normal animals Blood and urine sugars and D N ratios established in each instance the presence of severe diabetes

* Figures in parentheses indicate number of days after pancreatectomy

Table 1 summarizes the findings on glycogen synthesis in normal and diabetic cats at intervals of one, two and six hours after exercise. The following points are particularly noted

1 The lowering of muscle glycogen by exercise is essentially the same in normal and diabetic animals. There is no inability of the diabetic to break down glycogen on severe exercise. This agrees with the accepted facts

2 The actual amounts of glycogen laid down in the recovery period amply exceed the errors of the method (± 50 mg) and are larger than those obtained by most other workers

3 The glycogen recovery when expressed as the percentage of the amount lost is the same in the diabetic as in the normal for intervals of one and two hours

4 At six hours, however, a distinct difference is apparent. From the second to the sixth hour the normal animal has added 20 per cent of the lost glycogen to its muscles. The diabetic animal has remained almost stationary during this time. Other experiments not tabulated here have confirmed this. These consist of measurements of the synthesis occurring

FIG 1

from the second to the sixth hour and show that there is only a trace of glycogen added by the diabetic muscles while normal ones recover almost exactly 20 per cent of the glycogen lost during stimulation

Recovery periods of 24 hours have also been used. For these only one leg was stimulated and the animal allowed to recover from the anesthetic. Twenty-four hours later a second anesthesia for the removal of the legs was performed. Here we do not have figures to show the amount lost, but calculate the glycogen in the stimulated leg in terms of the resting glycogen in the opposite unstimulated leg. At the 24 hour interval both normal and

diabetic muscles have restored their glycogen to the level of the unexercised side

Figure 1 illustrates the time relationship of glycogen resynthesis in normal and diabetic animals. It clearly shows the essential points of difference between glycogen formation with and without the presence of insulin. This consists of a delay, or slowing of the resynthesis in the later part of recovery.

Table 2 shows the blood sugars in these animals. The glucose values

* Figures in parentheses indicate number of days after pancreatectomy

are what one expects for normal and diabetic animals. They serve to remind us that in the diabetic glycogen is being laid down in the presence of a very high blood sugar. The work of Major and Mann previously cited shows the importance this may have as a possible compensation for the lack of insulin.

How are these facts related to our general conceptions of carbohydrate metabolism? The fact that muscle glycogen is well maintained in diabetes

agrees with all that we know on this subject, the fact that there is a retardation of the resynthesis after exercise explains certain results that have been noted. The deficiency of glycogen formation in the diabetic is one of rate. The process takes place, but more slowly than in the normal. With respect to muscle glycogen, and disregarding for the moment the other features of the disease, one must consider the possibility that in diabetes the hyperglycemia may have a compensatory influence. It follows that, in its effect on glycogen formation, insulin seems to act as a catalyst in accelerating, at a low blood sugar level, a reaction that will take place slowly at a high glucose level if the hormone is absent. This must not be taken to mean that insulin acts directly to form glycogen. In reviewing the relation of insulin to glycogen formation last year, Macleod⁸ concluded that glycogen must be influenced secondarily to other changes. This idea is compatible with our experiments. The results imply that insulin is not related directly to glycogen formation in the tissues since glycogen is formed so well in its absence.

It has been demonstrated in the diabetic animal and in severely diabetic patients that there is no elevation of the respiratory quotient during recovery from exercise. The R/Q remains at the fat level and gives no evidence of carbohydrate combustion. This may be assumed to be the case in our experiments and leads to a consideration of the possible sources of the glycogen. (1) Lactic acid and hexosephosphate may account for much that is formed during the first one or two hours. Thereafter we must consider (2) that glycogen is formed from glucose, (3) from fat, or (4) that it depends on some unknown intermediate product of metabolism. Whatever source of glycogen is postulated, the fact remains that its formation can occur independently of the oxidation of carbohydrate and in the absence of insulin. Certainly in muscle glycogen synthesis after exercise there is one phase of carbohydrate metabolism that is independent of insulin.

If other work supports these facts and implications, perhaps they will be of value as one step in a process of elimination. If the large quantity of carbohydrate held as muscle glycogen is not primarily involved in diabetes, we may have excluded one false trail in the search for the fundamental disturbance in this disease.

In transferring these results to clinical diabetes it is noted that the mechanism for muscular contraction is preserved in this condition, i.e., in the absence of insulin. The breakdown of glycogen during exercise does not differ from the normal. The subsequent restoration of glycogen occurs without the presence of insulin although the process then requires a longer time for completion. The smaller breakdown of glycogen as well as the slower recovery may explain why exercise that is not too severe and that is followed by adequate rest has been found most beneficial to the diabetic. Practically, such considerations are modified by the amount of insulin available to the individual.

To summarize, there exists in the diabetic organism a marked capacity to
